Hemipenial morphology has been used to define taxonomic groups in Crotalinae (Campbell and Lamar 2004; Vellard 1946), and although Southern Hemisphere species share general characteristics, such as short and calyculate lobes rounded distally, subtle differences are expected, as in the number and size of spines. Indeed, hemipenial characters are closely associated with species differentiation, and thus are useful in evolutionary studies (Jadin et al. 2010).

The study of chromosomes is potentially useful for species definition and systematics, especially when external morphological characters are not sufficient for the clarification of taxonomic problems (Roze 1996). However, chromosomal data are rarely used for the characterization and differentiation of snake species. The karyotype has been described for few Brazilian snake species, and the paucity of data is especially acute for species from the Amazon Basin. There are no chromosomal data for *B. hyoprora* available in the literature. The chromosomal characterization of *B. hyoprora* will allow comparison with individuals of this species from other localities, with other species of this genus, and with individuals of sister-groups, assisting in the tracing

of patterns of chromosomal evolution in snakes.

Considering the lack of basic data for *B. hyoprora*, we present information about geographic range, hemipenial characteristics, and morphology. Morphological data were obtained from expeditions throughout the Brazilian Amazon plus herpetological collection databases and data available in the literature. In addition, we present for the first time the karyotype of *B. hyoprora*.

MATERIALS AND METHODS

Our data are based on independent sampling expeditions in northern Brazil, in the states of Amazonas, Mato Grosso, and Rondônia (Fig. 1). We found *B. hyoprora* specimens using diurnal and nocturnal visual searches, and in line with the recommendations of Franco and Salomão (2002), we deposited the specimens in the herpetological collection of the Instituto Nacional de Pesquisas da Amazônia, Manaus, Brazil. We used additional data from Herpetological Collections of Instututo Nacional de Pesquisas da Amazônia (INPA-H), Manaus and Museu de Zoologia of the Universidade de São Paulo (MZUSP), plus Coleção Zoológica de Vertebrados da Universidade Federal de Mato Grosso (UFMT-R), Cuiabá (Fig. 1).

Morphometric and meristic data.—We measured snout–vent length (SVL) and tail length (TL) with an accuracy of .01 millimeter. We determined the sex of the specimens by presence or absence of hemipenes, using a small subcaudal incision. We determined scutellation patterns by counting dorsal scale rows (D), ventrals (V), subcaudals (SC), cloacal (C), supralabials (SL), and infralabials (IL).

Hemipenial Morphology.—We prepared the right hemipenis from a preserved specimen, following the methods of Pesantes (1994). A 2% KOH solution was injected through the proximal end, hemipenis was immersed in KOH 2% solution to regain flexibility, and was filled with agar powder dissolved in distilled water. For hemipenial morphological terminology we followed Dowling and Savage (1960), Guo et al. (1999), and Jadin et al. (2010).

Chromosomal Techniques.—Karyotype analysis was conducted on a male *B. hyoprora* from the Parque Nacional Nascentes do Lago Jari (INPA-H 28044, see Fig. 1). Prior to preparation of the cell suspension, the individual was kept at 37°C for 24 h to induce mitosis. Mitotic chromosomes were obtained from intestine, liver, testicle, and spleen using the Ford and Harmerton (1956) "air-drying" method with modifications.

We used 0.2% colchicine at a proportion of 0.2 mL/10 g of body weight. After four hours we euthanized the snake using a veterinary anesthetic. We hypotonized cell material using 0.075 M potassium chloride solution, fixed in Carnoy fixer and stained with Giemsa. To locate the nucleolar organizer region (NOR), we used $AgNO_3$, following Howell and Black (1980). We organized chromosomes in decreasing size order and separated into groups by morphological type.

Chromosome morphology was determined based on the position of the centromere as described by Levan et al. (1964). We considered only macrochromosomes in the determination of the number of arms [fundamental number (FN)].

RESULTS

We examined nine *B. hyoprora* specimens—five males: 171, 209, 270, 352 and 375 mm SVL; and four females: 295, 437, 465 and 515 mm SVL (Table 1; Appendix I). One specimen (UFMT-R 9391) was found in 1990 in the municipality of Alta Floresta d'Oeste, Rondônia (11.97833°S, 61.96166°W; datum WGS 84, as for all subsequent geocoordinates listed; Fig. 1). The second specimen (INPA-H 17135) was found on 17 May 2006, in the Reserva Extrativista do Baixo Juruá, municipality of Juruá, Amazonas (03.47277°S, 66.02638°W). Two specimens (INPA-H 26570, 26571) were found on 29 January 2009, in forested areas at the edges of the Highway BR-319, municipality of Manicoré, Amazonas, with 100 km of distance between them (04.98666°S, 61.56638°W, and 05.58777°S, 62.18472°W). A fifth specimen (INPA-H 28044) was found on 28 March 2011, in Parque Nacional Nascentes do Lago Jari, municipality of Tapauá, Amazonas (05.81527°S, 63.15361°W). The last specimen (INPA-H 28516) we also found along the edges of the Highway BR-319, in the municipality of Borba, Amazonas (04.41472°S, 60.92444°W), on 03 September 2011. One INPA-H specimen (INPA-H 26527) was found on 10 September 2009, in the municipality of Trairão, western

TABLE 2. Morphological features of hemipenis of a specimen of *Botrocophias hyoprora* (INPA-H 26570).

Character	Description
Biconic lateral lobe shape	"C" shape
Shape of lobes bifurcation	"U" shape
Spines on each lobe in the sulcate face	18–19
Spines on each lobe in the asulcate face	14–20
Length of spines in the sulcate face (mm)	1.3–3.1
Length of spines in the asulcate face (mm)	1.16–2.71
Maximum width at the middle of lobes (mm)	5.17

Pará (04.63555°S, 55.46444°W), extending the distribution of the species 939 km in straight line to northeast from the nearest record (Mendes-Pinto and Souza 2011). Two MZUSP specimens were from the municipalities of Aripuanã (10.13888°S, 59.42638°W, collected on 11 November 1996) and Juruena (12.86388°S, 58.94944°W, collected on 19 June 1997), state of Mato Grosso. The record from Juruena extended the known distribution of the species 437 km in straight line to the south from the nearest record (Reserva Biológica do Jaru, Rondônia)

We included two additional non-collected specimens on the geographical distribution map, one from the municipality of Borba, Amazonas (04.43416°S, 59.63111°W; INPH-HF 9760, observed by A. P. Lima; Fig. 2A), the other from Fazenda São Nicolau, municipality of Cotriguaçu, Mato Grosso (09.85833°S, 58.41222°W; INPA-HF 9761, observed by J. C. de Noronha; Fig. 2B), extending the distribution of the species by 387 km in straight line East from the nearest record (Reserva Biológica do Jaru, Rondônia).

Hemipenial morphology.—The hemipenis is bilobed (Fig. 3A, B) and when everted extends to the level of the 10th subcaudal scale. The *sulcus spermaticus* bifurcates to 2.72 mm from the bifurcation of the lobes, at the level of 4–5th subcaudals. The lobes are about 1.5 times longer than the hemipenial body. Approximately one third of the lobes are calyculate, and two thirds are covered with spines. The division between calyculate and spinous areas is well demarcated. Spines increase in size towards the outer edges of lobes, with lengths of up to 3.1 mm in the sulcate side, and to 2.71 mm in the asulcate side (Table 2). Three transverse series of spines are present in the medial portion of internal edges of the lobes. The base of the organ is covered by about 20 small, well-spaced spines, both in the sulcate and asulcate sides. There is no clear differentiation between ornaments on the asulcate and sulcates sides of the hemipenis. Lips of the *sulcus spermaticus* are well marked in the calyculate area, inconspicuous on the spinous area, and make it clearly visible at the base of the organ, where it forks.

Chromosomal characterization.—A total of 30 metaphases were analyzed, all from liver cells. The diploid number is 36, comprised of 16 macrochromosomes (14 m–sm, 2 st) and 20 microchromosomes. The pairs 1, 3, 4, and 7 were metacentric; the pairs 2, 5, and 6 submetacentric and FN = 32 (Fig. 4A). It was not possible to determine the pair of sex chromosomes, because the analyzed individual was a male and, in snakes, females are the heterogametic sex. A nucleolar organizer region was found in the terminal region of three microchromosomes (Fig. 4B), suggesting a multiple system.

DISCUSSION

The geographical range of *B. hyoprora* determined by this study extends the distribution 1787 km SE (straight line) from the type locality at La Pedrera, Colombia (Amaral 1935), 939 km NE and 437 km S (straight line) from the Reserva Biológica Jaru, Rondônia (Bernarde et al. 2008), the nearest locality previously documented.

The scale counts were similar to those presented by Gutberlet and Campbell (2001), with little variation in the number of ventrals (123–128 in males, 123–131 in females), subcaudals (46–50 in males and females), and supralabials (7/7 or 7/8) scales (Table 1). The specimen from Alta Floresta d'Oeste, Rondônia (UFMT-R 9391) had a higher number of dorsal scale rows (25-25-20).

The general hemipenial morphology of *B. hyoprora* is consistent with all Crotalinae, strongly bilobed with clearly visible lateral spines, but scant information about the hemipenis of *Bothrocophias* has been published. All information contained herein was obtained from Campbell and Lamar (2004). *Bothrocophias myersi*, a closely related species, has a shorter hemipenis, reaching the second or third subcaudal when fully everted (10th in *B. hyoprora*), with bifurcation at the level of subcaudals 2-3 (4-5). Lateral spines in the *B. myersi* hemipenis are shorter and thicker than in *B. hyoprora*, and are distributed in longer rows, with 18–30 (14–20).

Several studies have been published on Neotropical pitvipers (e.g., Martins and Oliveira 2001; Turci et al. 2010), and many

species are relatively well known. However, among Neotropical pitvipers, *B. hyoprora* is possibly the least known species with regard to natural history, ecological patterns, and geographical range. This is due to the fact that the species is rarely recorded in field studies and poorly represented in herpetological collections. Our study was based on only seven collected specimens and two additional non-collected specimens, and this restricts the discussion of our results.

Some Neotropical pitvipers have been reported as the most frequently encountered species in field work, such as *Bothrops atrox* in the central Brazilian Amazon (Fraga et al. 2011; Martins and Oliveira 1998), and they can be good models for ecology or natural history studies. Even though this is a poorly known and rarely recorded species, we cannot assume that *B. hyoprora* is rare, or even that their population density is low, because there are still large sampling voids within the range of this species, where collecting attempts have not been made, especially in the Brazilian Amazon. The species is not currently on the IUCN Red List (IUCN 2011), but more long term systematic collections of snake populations in the Amazon Basin are needed to determine the population levels and abundances of all species.

Diet of *B. hyoprora* is not well known, but apparently they eat centipedes, amphibians, lizards, and small mammals (Bernarde et al. 2008). In this study we found remains (scales) of a snake in the digestive tract of a juvenile specimen (INPA-H 26571). Due to the advanced state of digestion, we were unable to identify the prey to more specific taxonomic levels.

This is the first time that the karyotype of *B. hyoprora* has been described. The chromosome number in snakes is a conservative character, with 2n varying between 24 and 56 (Oguiura et al. 2010). The karyotype reported here, 2n = 36 (16 macro and 20 microchromosomes), is the most frequently recorded type in those genera with close phylogenetic affiliations with *Bothrocophias*, such as the genus *Bothrops*, and also in basal families (Beçak et al. 2003; Gorman 1981; Oguiura et al. 2010; Pyron 2011). However, the morphology of chromosomes is not always similar among them, which means that chromosomal rearrangements are present. The NOR position is generally restricted to the microchromosomes, although some species show variation in the number of tagged chromosomes and, in some cases show this on macrochromosomes (Trajtengertz et al. 1995). Although *B. hyoprora* had only three chromosomes that stained with silver nitrate, this species probably has a NOR on four chromosomes, but only three were active.

Chromosome number and structure, including the number of macro- and micro-chromosomes, the position and morphology of pairs, their secondary constrictions, and the karyotypic formula are all useful characters for differentiating among species in the genus *Micrurus* (Serafin et al. 2007). Considering 2n = 36 (16 macro, 20 micro) to be the ancestral karyotype for the genus, two general evolutionary patterns were suggested: Central American species had a tendency for a decrease in the number of chromosomes, while those in South America had a tendency to increase this number. Although *B. hyoprora* possesses the putative ancestral pattern (Fenwick et al. 2009), it is not possible to reach a conclusion regarding chromosomal evolution, given that chromosomal information is not yet available for other members of this genus. Further karyotypic work on the genus *Bothrocophias* and also on the Viperidae in general will doubtless reveal evolutionary patterns.

A Galápagos Ectothermic Terrestrial Snake Gambles a Potential Chilly Bath for a Protein-Rich Dish of Fish

The Galápagos Islands are well known for their adaptive radiation of plants and animals (Grant 1986; Itow 1994). It seems logical that organisms should take advantage of new opportunities when they colonize new habitats. On the wild black shores of Fernandina Island, located on the extreme west of the Galápagos Archipelago, the coast is still taking shape under the action of recent eruptions (1995, 2005, and 2009; Smithsonian Institution Global Volcanism Program) from this extremely active shield volcano. This is particularly true of the west coast, which is bathed by cold productive upwellings from the Equatorial Cromwell Under Current. Two locations, Capes Douglas and Hammond, have not been flooded by fresh lava in the recent past and are havens for life, including fur seals, flightless cormorants, and marine iguanas.

Of the four species of xenodontine colubrid snakes reported from the central and southern Galápagos Islands, Fernandina has two species: *Antillophis slevini*, (Fernandina, Isabela, and Pinzon) and *Pseudalsophis biserialis occidentalis* (Fernandina, Isabela, and Tortuga) (Thomas 1997). The latter species is common on the western shorelines, but not exclusive to them. Here we report on a previously unpublished account of *Pseudalsophis biserialis occidentalis* feeding on an unsuspected prey, marine fish.

Setting.—Fernandina is a very young active shield volcano built over the Galápagos hotspot. Its coasts are composed of raw black basaltic lava with the west coast dominated by vertical cliffs often beaten by incoming swells. However, on the northwestern cape (Douglas), a low fractured level ledge of pahoehoe lava extends seaward (Figs. 1a, b). Just to the north of the southwestern cape (Hammond), a sand beach backing a semi-circular tidal pool protected by a boulder ramp is nestled between massive fields of rough a'a lava (Figs. 1a, c). At both of these places exist large populations of Fur Seals (*Arctocephalus galapagoensis*) and Marine Iguanas (*Amblyrhynchus cristatus*), in addition to Flightless Cormorants (*Phalacrocorax harrisi*), Galápagos Lava Lizards (*Microlophus albermarlensis*), and the aforementioned snakes (*Pseudalsophis biserialis* and *Antillophis slevini*), both of the latter being very common. Galápagos Hawks (*Buteo galapagoensis*) have territories in both places.

Fish as prey of Pseudalsophis biserialis occidentalis.—On four separate occasions spread over 14 years from 1995–2009, *P. b. occidentalis*, which mostly feed on lava lizards and recently born marine iguanas, have been observed by one of us (GM) to actively hunt coastal fish. This was also reported to Merlen by filmmaker Richard Wollecombe in 1999. This activity has not been previously described for any of the four species known from Galápagos nor from their mainland and Caribbean ancestors. On Fernandina it is common for snakes to be observed on barren lava shorelines and it has been presumed that they are searching for terrestrial vertebrate prey.

Hunting activities are now described:

1) At Cape Douglas a snake entered a lava contraction crack (approx. 3–10 cm in width) that led to the sea (Fig. 1b). On reaching the vertical shoreline at some 50–100 cm above sea level where the rock is wetted by spray and tidal water, the snake extended 1/4 to 1/3 of its body over the water. This habitat is occupied by the labrisomid endemic Four-eyed Blenny, *Dialommus fuscus*, which spends much of its life out of the water on the wetted surface of the rocks hunting small crustaceans. On one occasion it was possible to view the snake striking at the fish. The captured blenny was taken back into the crack and carried tail first onto the surface of the lava where it was consumed (Fig. 2). This practice has been observed twice: in August 1995 and November 2009.

2) On a post-1998 El Niño survey in the same area, a snake was captured for identification. During this process, the snake regurgitated its prey. Because the prey item was partially digested it was difficult to identify to species, but it was definitely a fish. Merlen sent this specimen to John McCosker, Curator of Fish at the California Academy of Sciences, for identification. It was provisionally placed in the myctophid genus *Bolinichthys*, possibly *B. longipes* (Fig. 2, inset). John Paxton, specialist in lantern fish at the Australian Museum in Sydney also examined an image of this specimen and considered *Bolinichthys* the most likely genus. This is remarkable as this genus forms part of the oceanic deep scattering layer fauna and no terrestrial snake has ever been recorded swimming there. The extreme steepness of the underwater topography off the west coast permits oceanic ecosystems to exist within "a stone's throw" of the shoreline, with myctophid fish and hatchetfish (Sternoptychinae) being killed in abundance by lava entering the coastal waters (McCosker et al. 1997; Merlen, unpubl. data 2009). Possibly the fish was moribund (ill or stunned by a predator such as a fur seal and drifted close in to the shore). Less likely is that the snakes swim at night for this prey, which is uniquely on the surface during darkness.

3) At Cape Hammond the small tidal lagoon and beach is surrounded by recent flows of lava (Fig. 1c). On the low tides much of the sandy rocky floor of the lagoon is uncovered but remains wet (Fig. 3, inset). There are many basaltic boulders and plates of apparently old slabs of volcanic rock permeated by small crevices and holes. In December 2008, 15 snakes were seen patrolling this habitat, investigating holes and the undersides of boulders apparently seeking prey. A snake was observed with 1/3 of its body length in a hole (Fig. 3). When extracted, the snake was ingesting a fish approximately 13 cm in length, apparently *Labrisomus dendriticus*, although the head and the distinctive spot on the gill plates were not visible (Fig. 4).

FIG. 1. A) Bathymetry and topography of Fernandina Island showing Cape Douglas and Cape Hammond and direction of cold productive upwelling waters (Ryan et al. 2009). B) Cape Douglas indicating exposed shelf where fish predation has been observed *(Image: Godfrey Merlen)*. C) Cape Hammond with protected tidal pool where 15 snakes have been observed at low tide seeking prey.

FIG. 2. Observed prey of Galápagos Snake at Cape Douglas. Coastal endemic Four-eyed Blenny, *Dialommus fuscus*. Inset: Alternate prey item: Oceanic Lantern Fish, *Bolinichthys longipes* (used with permission from The Fish Database of Taiwan).

FIG. 3. *Pseudalsophis biserialis occidentalis* exploring hole in bed of tidal pool at Cape Hammond. Inset: Bed of tidal pool at Cape Hammond. Snake can be seen in foreground.

FIG. 4. *Pseudalsophis biserialis occidentalis* consuming fish (probably *Labrisomus dendriticus*, Labrisomidae) after extracting it from a hole in an intertidal rock.

Observations are unknown between these two west coast locations (18.7 km approximately), a little-walked and risky landing stretch of coastal cliff, nor are there recordings from the east coast of Fernandina, which is much more frequently visited. On the present limited data it appears that a piscivorous diet, for at least some snakes, is limited to, and to small areas of, the west coast.

Discussion.—Because there are so few observations available, conclusions beyond the presence of piscivory in *Pseudalsophis biserialis occidentalis* are not possible. Nevertheless it may be interesting and useful to state a few observations concerning snakes and their habits on Fernandina. There are striking differences in habitat possibilities on the east and west coasts of the island. Although all coastal areas are composed of rough open lava rock, the east coast offers a considerable mangrove habitat with numerous small beaches and sea lion colonies. This diverse habitat may offer greater variety and abundance of prey items, especially endemic rats, of which there are two species on this island (*Nesoryzomys narboroughi* and *N. fernandinae*), lava lizards *Microlophus albermarlensis* (which are subdued by constriction) (Merlen, unpubl. data), and the ubiquitous Marine Iguana, *Amblyrhynchus cristatus*. The west coast is a harsh, virtually treeless environment, yet is brushed by some of the most productive waters of the archipelago. Perhaps in the two areas where low-lying land suitable for snakes reaches the sea, Cape Douglas and Cape Hammond, *P. b. occidentalis* have been able to take advantage of this novel environment for a diet of fish.

The observation of 15 snakes at one time around and in the damp basin of the tidal pool at Cape Hammond suggests that fish hunting is not a unique habit of one individual, but one that has spread through, at least, the local population.

A final remark concerns predation. Snakes investigate holes in the bottom on the pool at Cape Hammond (Fig. 3). In order to do so an estimated 1/3 of the body was inserted. This exposes the rest of the body to attack from above because these probing searches are often under open skies. Tjitte de Vries, a specialist on the Galápagos Hawk, has observed on one occasion a snake in the talons of a hawk on Santa Fe Island (de Vries, pers. comm.). Hawks have territories at both Cape Douglas and Cape Hammond. We assume that this predation is not common on Fernandina and is not a deterrent to snakes feeding in exposed holes.

Conclusion.—Predation on marine fish by snakes appears to be a unique habit of *Pseudalsophis biserialis occidentalis* on the west coast of Fernandina, especially at Capes Douglas and

Hammond. We do not know when its ancestor, *Pseudalsophis elegans* (fide Thomas 1997) arrived in the archipelago, but today three subspecies of *P. biserialis* span the central and southern islands. The spread to Fernandina has been recent, less than 70,000 years, (Geist et al., unpubl. ms.) and yet it appears that a new niche for coastal fish predation has been occupied by an adaptable colubrid snake.

Acknowledgments.—We thank the Direction of the Galapagos National Park for authorizing visits to Fernandina island. In particular, GM thanks Wacho Tapia of the Galapagos National Park for his enthusiastic support.

Conserved Ontogeny of Color Pattern Leads to the Misdiagnosis of Scincid Lizards of the *Plestiodon skiltonianus* Species Complex

Skinks of the *Plestiodon skiltonianus* species complex, which includes the Western Skink (*P. skiltonianus*), the San Lucan Skink (*P. lagunensis*), and Gilbert's Skink (*P. gilberti*), can be very difficult to distinguish unless geographic information accompanies the specimen. This is due to similarity in the ontogeny of color pattern among the different recognized taxa, regional polymorphism in scale and color pattern characters, and a lack of fixed character differences that reliably distinguish each species across the range of the complex (Rodgers and Fitch 1947; Taylor 1935). Some authors have suggested that *P. skiltonianus* and *P. gilberti* be treated as conspecific (e.g., Camp 1916; Cope 1900; Grinnell and Camp 1917; Van Denburgh 1896), and certain statements in the literature (e.g., "…young [*P. g. gilberti*] specimens are marked just like the young and most adults of *skiltonianus*" [Smith 1946, p. 385]) have only added to the confusion. Phylogenetic analyses have also done little to resolve these taxonomic issues, as separate *P. gilberti* lineages have evolved multiple times within a paraphyletic *P. skiltonianus* (Brandley et al. 2012; Richmond and Reeder 2002), and species delimitation varies widely depending on the concept of species (Richmond and Jockusch 2007; Richmond et al. 2011). For the remainder of the paper, we place the name "*gilberti*" in quotation marks to reflect the nonmonophyly of these lineages except where *P. gilberti* is specifically referred to in earlier studies.

The main characters used to distinguish members of the *P. skiltonianus* complex in the field include body size, dorsal color pattern, tail color (pink vs. blue), and to a lesser degree limb length, supralabial count, nuchal scale count, and a few others related to scalation (Grismer 1996; Rodgers 1944; Rodgers and Fitch 1947). Size (SVL) can be effective for differentiating adult individuals in most areas, but is of little use for young specimens. Color pattern is useful to a degree, but dorsal stripes are retained longer into adulthood in certain *"gilberti"* populations than in others, especially in females, and in some areas the stripes are often never completely lost. Aberrantly large *P. skiltonianus* also have very degraded, or in some cases, no stripes at all (JQR, pers. obs.). Juvenile tail color is useful in regions where pink-tailed *"gilberti"* approach or are syntopic with *P. skiltonianus*; however, *"gilberti"* populations in the northern and central Sierra Nevada, as well as in scattered populations in the east Mojave Desert and the Panamint Mountains, are blue-tailed. Allopatry and different juvenile tail colors distinguish juvenile *P. lagunensis* in southern Baja California from *P. skiltonianus* in northern Baja California, but the adult phenotypes of the two species are similar enough that some authors have regarded them as conspecific (Linsdale 1932; Schmidt 1922; Stejneger and Barbour 1933; Tanner 1988).

One of the most widely used characters for distinguishing juveniles of *P. skiltonianus* and "*gilberti*," aside from tail color when the differences are obvious, is the distance that the dark lateral stripes extend onto the tail (Fig. 1). In various field guides and species descriptions, it is commonly stated that this stripe extends much further in *P. skiltonianus* (ca. 1/3 to 1/2 way down the tail) than it does in "*gilberti*"; in the latter, this stripe purportedly ends at the base of the tail just posterior to the hind limbs (Behler and King 1979; Jones and Lovich 2009; Lemm 2006;

FIG. 1. Example of the lateral tail stripe character in a juvenile *Plestiodon skiltonianus* from Tehama County, California (ca. 520 m elev.).

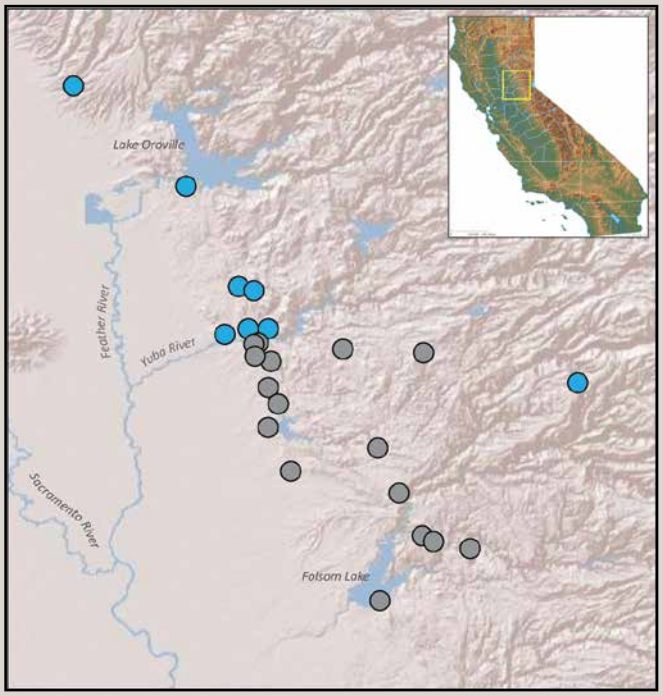

FIG. 2. Map of the Yuba River study region indicating DNA sampling locations for *P. skiltonianus* (blue dots) and *P. "gilberti"* (gray dots). The outlier *P. skiltonianus* locality south of the Yuba River represents a high elevation population at Red Point, Placer Co. (~1430 m), first published in Rodgers and Fitch (1947) and revisited during this study. Several additional high elevation populations from this region referred to as either *P. skiltonianus* or *P. "gilberti"* in museum collections have not yet been sequenced and require taxonomic attention.

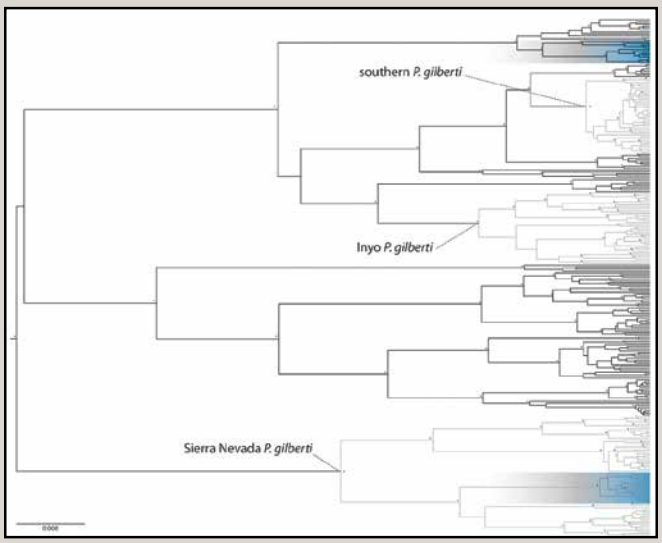

FIG. 3. Maximum clade credibility tree for ND4 mitochondrial haplotypes within the *P. skiltonianus* group; the tree was estimated using a model partitioned Bayesian analysis in BEAST v1.7 (Drummond et al. 2012; 20×10^6 iterations with a 10% burn-in). Gray branches denote separate "*gilberti*" lineages; black branches denote *P. skiltonianus*/*P. lagunensis*. Bullets indicate posterior probabilities ≥ 0.95. Shaded blue-gray boxes highlight haplotypes recovered on the north (*P. skiltonianus*) and south sides (Sierra Nevada "*gilberti*") of the Yuba River, California.

Macey and Papenfuss 1991; Rodgers and Fitch 1947; Smith 1946; Smith and Brodie 1982; Stebbins 2003; Stebbins and McGinnis 2012; Storer et al. 2004; Tanner 1957, 1988). However, like the other characters used to differentiate *P. skiltonianus* and "*gilberti*," we have detected notable variation in the extension of the lateral tail stripe in populations of both species, and below we present data that describe how the character fails to differentiate the two in certain parts of the range.

During recent survey work on *Plestiodon* populations in the western foothills of the northern Sierra Nevada in Yuba County, California, we discovered what appeared to be juvenile *P. skiltonianus* just south of the Yuba River in an area that is reported to be exclusive to "*gilberti*," based on the bright blue tail color and the continuation of the dark lateral stripe well past the hindlimbs (Rodgers and Fitch 1947). A longstanding notion exists that *P. skiltonianus* is essentially restricted to the north side of the river, which runs perpendicular to the Sierra Nevada, and that the range of "*gilberti*" extends north to the Yuba River from the south but does not cross it (Rodgers 1944; Rodgers and Fitch 1947; Stebbins 2003; Fig. 2). Only four isolated *P. skiltonianus* populations have been formally documented from the immediate south side of the Yuba River (Rodgers and Fitch 1947; specimens MVZ 190472,190479; this study), occurring mainly in the conifer zone at approximately 900–1450 m, whereas "*gilberti*" occurs at lower elevation in blue oak woodland and grassland only on the south side of the river. This purported distribution is perplexing, as there are no salient habitat differences on either side of Yuba River, and none of the other major river drainages south of Yuba County have presented barriers that limit the distribution of "*gilberti*" along the western slope of the Sierra Nevada (although they may have intermittently in the past). Thus, we were not surprised to find *P. skiltonianus* south of the Yuba River. Because both species were expected to have blue-tailed juveniles and scale counts were ambiguous, our identification of juvenile specimens relied mainly on the degree to which the dark, lateral stripe extended onto the tail.

To confirm our identifications, we extracted DNA from small tail clips (~ 10.0 mm) preserved in 95% ethanol from 28 individuals and sequenced 16 for their ND4 mitochondrial haplotypes (~1500 bp: Dryad repository: doi:10.5061/dryad.2873b). We then compared these sequences to a large ND4 dataset representing the entire range of the *P. skiltonianus* complex (Fig. 3). *Plestiodon skiltonianus* and "*gilberti*" in Yuba County (the latter regarded as *P. g. placerensis*; de Quieroz and Reeder 2012) have high mitochondrial sequence divergence and are easily distinguishable based on their haplotypes (Richmond and Jockusch 2007; Richmond and Reeder 2002). Surprisingly, we found that all skinks sampled on the south side of the Yuba River below 1430 m had

FIG. 5. A) Juvenile *Plestiodon skiltonianus* from just north of the Yuba River, California (ca. 265 m elev.); B) Juvenile "*gilberti*" from just south of Yuba River (ca. 100 m elev.); C) Juvenile "*gilberti*" from Tuolumne County, California (ca. 785 m elev.) showing lateral tail stripe stopping closer to the hind limbs, but still extending notably past them.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

Sierran "*gilberti*" haplotypes, and all those sampled on the north side of the river regardless of elevation had pure *P. skiltonianus* haplotypes, consistent with the supposition of Rodgers (1944) and Rodgers and Fitch (1947). We also noted that while adult male "*gilberti*" in this area completely lose the striped color pattern, as is generally the case for "*gilberti*," adult females retain dark lateral stripes on the flanks and well onto the tail, immediately below the area where the light dorsolateral stripe runs along the body axis in juveniles (Fig. 4; also noted in Rodgers 1944). This same pattern has been noted in other parts of the species' distribution (e.g., creeks along the eastern slopes of California's inner Coast Ranges; JQR, pers. obs.), where lateral stripes extend well beyond the hindlimbs even in some of the largest adult females. Thus, a character that is typically lost early in ontogeny in some parts of the "*gilberti*" range, or is absent altogether, is retained in adult females in other areas, particularly the northern Sierra Nevada.

In his description of *P. g. placerensis*, Rodgers (1944) did not address the lateral tail stripe character, and later accounts identifying this and other *P. gilberti* subspecies provide information about tail color (pink or blue), supralabial count, but little else (e.g., Jones and Lovich 2009; Stebbins 2003). Rodgers and Fitch (1947) provided qualitative descriptions of the ontogeny of *P. skiltonianus* and the different forms of "*gilberti*," illustrating varying degrees in the loss of the dorsolateral stripes and the bright tail color. However, variation in the extension of the dark, lateral tail stripe for "*gilberti*" was not discussed. Consistent with the descriptions of Rodgers and Fitch (1947), we have found that hatchling, juvenile, and younger adult female "*gilberti*" (Fig. 4c)

in Yuba County appear to be *P. skiltonianus* upon initial inspection; in both forms, the tail color is bright blue and the lateral tail stripe extends well beyond the hind limbs (although the stripe may continue further on the tail in *P. skiltonianus* north of the Yuba River than it does in "*gilberti*" south of the Yuba River [Fig. 5a, b]). The similarity in this character between species fades further south in the Sierra Nevada foothills (Fig. 5c), where the dark lateral stripe ends closer to the base of the tail in young "*gilberti*."

Because of the variability of this character across the range of the species complex, we consider it unreliable for distinguishing *P. skiltonianus* and "*gilberti*" over large portions of the range of the *P. skiltonianus* complex. Despite years of field collecting and DNA sequence data from hundreds of individuals (including sequences obtained from museum specimens that were incorrectly identified as *P. skiltonianus*), we have yet to recover a *P. skiltonianus* specimen from locations south of the Yuba River, with the exception of a single site at approximately 1430 m and 14 km SSE of the Yuba River, until Tulare County in the southern Sierra Nevada. We suspect that a number of museum specimens collected from this same region at lower elevation are incorrectly identified as *P. skiltonianus* and instead belong to the Sierran "*gilberti*" lineage as identified in Richmond and Reeder (2002). In fact, bright blue juvenile tail color and the continuation of the dark, lateral stripe past the hindlimbs are the two characters that appear largely responsible for these misidentifications.

Perhaps the most interesting finding of our survey work is that *P. skiltonianus* and "*gilberti*" are most similar in the ontogeny of color pattern where their distributions meet but do not overlap at the Yuba River. Yet in southern California where the two species are syntopic, for example, they are easily distinguished by juvenile and adult color pattern (*P. skiltonianus* juveniles have blue tails and light dorsal stripes throughout adulthood whereas juvenile "*gilberti*" have pink tails and no stripes as adults), and adult body size. In fact, adult body size is more divergent in southern California than anywhere else in the range of the species complex, and is a predominant factor contributing to their reproductive isolation (Richmond and Jockusch 2007; Richmond et al. 2011). This suggests that sympatry in southern California may have influenced phenotypic divergence of the two forms, whereas allopatry in the northern Sierra Nevada may have contributed to retention of the ancestral juvenile color pattern.

Acknowledgments.—We thank Robert W. Hansen for his photo of *P. gilberti* from Tuolumne County, California. Dustin A. Wood and two anonymous reviewers provided helpful comments on the manuscript.

A Non-Invasive Method of Measuring Heart Rates in Small Reptiles and Amphibians

Measuring the heart rate of animals is crucial to the work of many biologists, including applications in veterinary, physiological, through to ecological studies. Determining heart rate is valuable because it is an indirect indicator of metabolic rate (Bennett 1972; Bradford 1983; Butler et al. 2004; Greenvald 1971). As such, heart rate measurements can be a substitute for metabolic chamber and doubly-labelled water studies. Aside from the traditional methods of measuring heart rates such as electrocardiography and seismocardiography, recent technical advances have democratized the use of a variety of external or internally implanted data loggers (Altimiras et al. 2000; Woakes et al. 1995). The choice of method depends on the application (long-term field study versus lab work), and the size (technical difficulties arise in animals < 40 g) and type of animals used (i.e., importance of stress as a confounding factor). We suggest a simple and inexpensive method of measuring heart rate in small vertebrates (< 40 g) applicable to both field and laboratory studies.

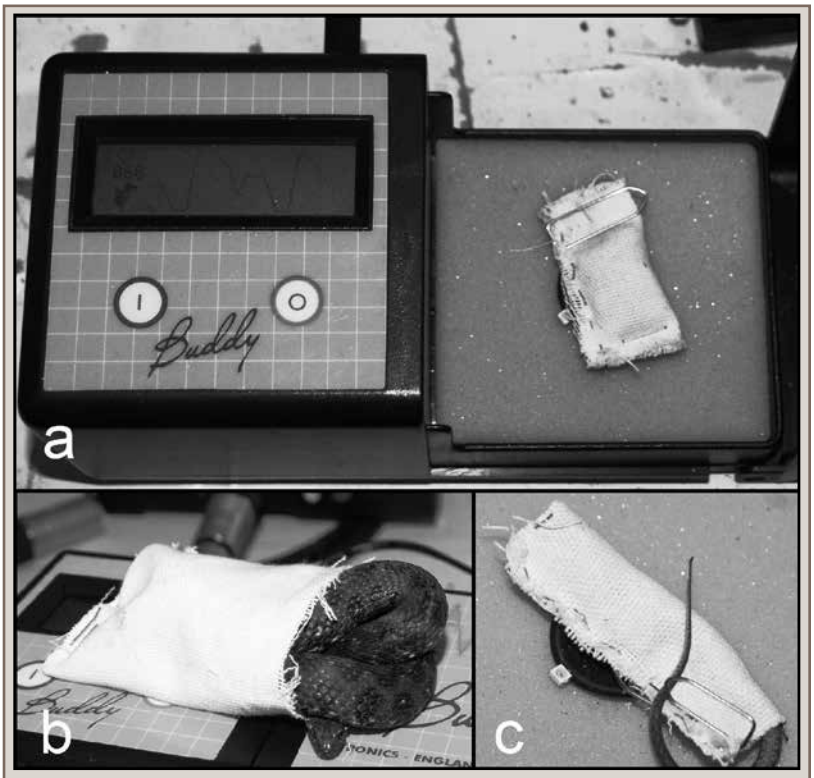

FIG. 1. Animals were placed into cotton material bags and acclimated to the testing temperature. Each bag was then gently lifted onto the sensor pad of the Buddy® monitor (panel A). A young Viperine Water Snake (*Natrix maura*) (panel B) and an adult Wall Lizard (*Podarcis muralis*) (panel C) are shown during testing.

Methods.—The Buddy® digital egg monitor (MK2, Avitronics) was developed for measuring heart rates of avian and nonavian reptile embryos for the poultry industry and research applications (Du et al. 2009; Lierz et al. 2006). The Buddy® system works by shining an infrared beam onto the surface of the egg, detecting minute distortions caused by embryonic heart beats (Du et al. 2009). Muscle impulses other than cardiac ones, as well as external vibrations, generate stronger signals than the study animal's heart beats, which preclude the monitor from measuring concurrent heart beats (Lierz et al. 2006).

Du and colleagues (2010) expanded the use of the monitor when they recorded heart rates in hatchlings of two emydid turtle species, *Chrysemys picta,* and *Graptemys pseudogeographica kohnii*. To do so, young turtles were placed into egg-shaped plastic balls and then onto the Buddy® monitor sensor pad. While this method worked effectively with turtle hatchlings that are roughly round in shape and fit into an egg-shaped plastic ball, we wished to extend this method to other small vertebrates, including elongated animals such as snakes, lizards, and newts.

The major problem faced when trying to record heart rates in small animals (rather than eggs) is immobilizing the animal on the Buddy® system sensor pad to avoid interference with the machine readings. To solve this problem, we made small cotton material bags of various sizes and shapes in order to accommodate

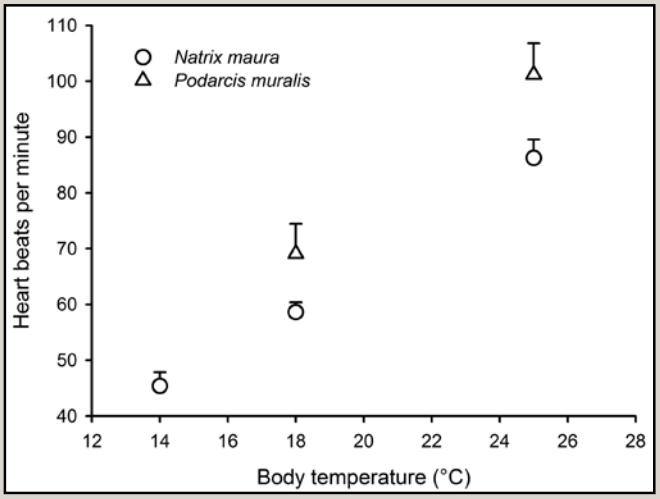

FIG. 2. Heart rates were recorded in eight Viperine Water Snakes (*Natrix maura*) at three body temperatures (14, 18, and 25°C) and 10 Wall Lizards (*Podarcis muralis*) at two body temperatures (18 and 25°C). In both snakes and lizards, heart rates significantly increased with body temperature (see text for details). Means ± standard errors are plotted.

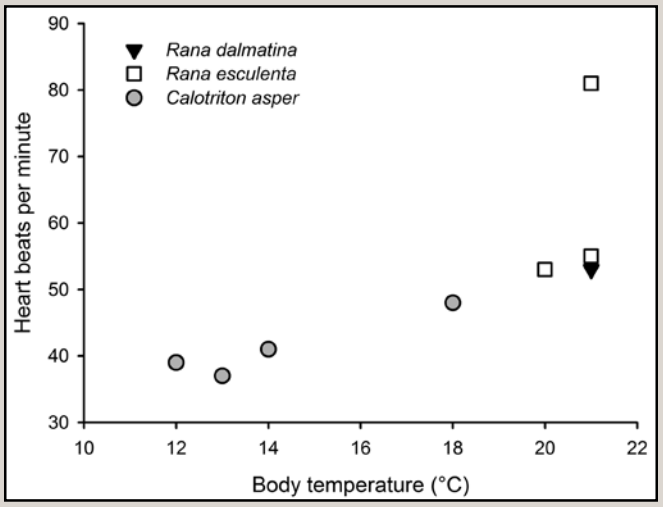

FIG. 3. Heart rate values recorded in three Edible Frogs (*Rana esculenta*), one Agile Frog (*Rana damatina*), and four Pyrenean Brook Salamanders (*Calotriton asper*) are shown. Data are plotted against body temperature.

the different individual snakes, lizards, newts and frogs we wished to test (Fig. 1). We first validated heart rate measurement obtained with the Buddy® egg monitor in young snakes against a proven method (echocardiography). We then recorded heart rates as a function of body temperature in snakes, lizards, newts, and frogs of varying sizes. Body temperatures were recorded with the temperature probe Trotec® BP20.

Because repeated measurements were made on the same individuals, we analysed heart rate measurements using Wilcoxon Matched Pairs Test when comparing two dependent samples, and Friedman ANOVA when comparing multiple dependent samples.

Validation of the method.—We measured heart rates in 12 captive *Natrix maura* (Viperine Water Snakes; born to six different clutches in September 2011; ranging from 4.6 g to 15.1 g in body mass and from 19.9 cm to 27.2 cm in snout–vent length [SVL]) using the Buddy® egg monitor and by echocardiography as a control proven method. Measurements were performed in a controlled temperature room (CTR) maintained at a constant 22°C within a Veterinary Hospital (Dr. Breuil and Feix; Toulouse, France). Light was dimmed inside the CTR to limit potential stress to the snakes. We used a balanced testing order: 6 snakes were first measured using the Buddy® egg monitor, then using an ultrasound device (Esaote® MyLab™30Gold Cardiovascular) and probe (SC3123 Microconvex 10 MHz), and *vice versa* for the remaining six snakes. Snakes were maintained in plastic boxes Exo-Terra® (30.0 × 19.5 × 20.5 cm) and acclimated to ambient temperature for a minimum of 30 minutes prior to testing. Three heart rate readings were taken with each snake and each technique, from which we calculated average heart rates. Each series of measurements was completed in under 5 minutes, and snakes were allowed to rest 5 minutes between the two measurement series (total experimental time for each snake: 15 minutes). There was no significant difference in individual average heart rates between the two techniques: heart rates averaged 104.78 ± 7.16 BPM according to the ultrasound method and 103.17 ± 10.91 BPM using the Buddy® egg monitor (Wilcoxon Matched Pairs Test; N = 12; T = 34.00; Z = 0.39; P = 0.70).

Heart rates as a function of body temperature.—We measured heart rate in eight captive born *Natrix maura* originating from 5 different clutches (three juveniles captive born in August 2011 and five neonates captive born in August 2012). Snakes ranged from 2.1 g to 21.2 g in body mass, and from 12.6 cm to 35 cm in SVL. Each individual was tested at three different body temperatures (14, 18, and 25°C) on three consecutive days applying a balanced order design. Snakes were placed inside their individual testing bags, and into temperature controlled chambers for 30 minutes in order to reach testing temperature and ensure minimum stress levels at the time of testing. As expected, heart rates significantly increased with body temperature (Friedman ANOVA; $\chi^2_2 = 16.00$; P = 0.0004; Fig. 2).

We measured heart rate in 10 field-caught Wall Lizards (*Podarcis muralis*) using the same protocol (see Fig. 1). Lizards ranged from 3.2 g to 7.5 g and from 52.1 mm to 65.6 mm in SVL. Heart rates measured at 25°C were significantly greater than heart rates measured at 18°C (Wilcoxon Matched Pair Test; N = 10; T = 0.01; Z = 2.80; P = 0.0005; Fig. 2). In addition to lizards and snakes, we also used the Buddy® system to measure heart rates in frogs and salamanders. We measured heart rates in three Edible Frogs (*Rana esculenta*) that ranged from 22.7 g to 64.7 g body mass and 61.0 mm to 81.9 mm body length, one Agile Frog (*Rana dalmatina*) (body mass = 35.0 g; SVL = 75.0 mm), and four specimens of the Pyrenean Brook Salamander (*Calotriton asper*) that ranged from 7.5 g to 11.0 g in body mass and from 64.0 mm to 82.0 mm in SVL (Fig. 3).

Applications.—The possible applications of the Buddy® system to record heart rates in small animals are broad, although some fine tuning may be necessary depending on the model system and the conditions of use. For instance, heart rate detection was straightforward in snakes and frogs (heart rates usually stabilized in under 30 sec), but required more repositioning of the bag when measuring a lizard or a newt (perhaps due to their more rigid elongated shape and impossibility to coil into a ball shape). However, differently shaped sensor pads might be developed and work better on differently shaped animals. Notably, it might be possible to fine tune this method to recording heart rates in small mammals (mice, bats etc.) as well as small birds.

In conclusion, the main advantages of using the Buddy® system are that the unit is affordable, accurate, transportable, and can be battery operated; and therefore may be used in remote field locations. Using the system in the laboratory provides researchers with a quick and easy tool to record heart rates (and incidentally metabolic rates) in small animals without relying on high maintenance or expensive (and sometimes fragile) machinery or data loggers.

Acknowledgments.—Funding was provided by the Centre National de la Recherche Scientifique (CNRS), the University Paul Sabatier Toulouse (project entitled EXUVIE), and the Agence Nationale pour la Recherche (ANR project INDHET). Capture permit was issued by the Direction Régionale de l'Environnement, de l'Aménagement et du Logement (DREAL, permit # 2012-10). We complied with all applicable institutional animal care guidelines. We wish to thank Olivier Guillaume for his help with accessing the colony of *Calotriton asper*, and Dr. Lugardon for ultrasound measurements. This work is part of the "Laboratoire d'Excellence" (LABEX) entitled TULIP (ANR-10-LABX-41).

Evaluation of Traps to Capture Eastern Hellbenders (*Cryptobranchus alleganiensis alleganiensis*) in Deep Water Habitat

Cryptobranchus alleganiensis (Hellbenders) are large, aquatic salamanders that prefer streams and rivers with moderate to swift-flowing water with large rocks. *Cryptobranchus alleganiensis* individuals are mostly nocturnal, remaining under large rocks and in bedrock crevices during the day and emerging at night to forage primarily on crayfish with fish, insects, worms, snails, frogs, etc., accounting for secondary dietary items (Petranka 1998). Two subspecies are currently recognized, both restricted to the eastern United States: *C. a. alleganiensis* (Eastern Hellbender) and *C. a. bishopi* (Ozark Hellbender; Crother et al. 2012), and both subspecies have experienced population declines throughout much of their range, especially in Missouri (Briggler et al. 2007; USFWS 2011; Wheeler et al. 2003). *Cryptobranchus alleganiensis* population declines in Missouri are mainly linked to habitat degradation and alteration, water quality, commercial exploitation, predation, and disease (Briggler et al. 2010; Briggler et al. 2007; USFWS 2011).

A wide array of capture methods have been used to sample *C. a. alleganiensis* (Foster et al. 2008; Nickerson and Krysko 2003; Williams et al. 1981). A thorough review and critique of the various methods can be found in Nickerson and Krysko (2003) and Browne et al. (2011). Snorkel diving coupled with turning rocks has been and continues to be the most effective method for capturing *C. alleganiensis* (Browne et al. 2011; Foster et al. 2008; Nickerson and Krysko 2003). This technique works well for shallow to moderately deep (< 2 m), clear water streams; but sampling turbid (Secchi depth < 1 m), deeper water habitat is difficult, if not impossible, with this method.

Anglers have reported catching *C. alleganiensis* on hook and line (Beck 1965; Dundee and Dundee 1965; Ferguson 1961; Gates et al. 1985; Wortham 1970) or hoopnets (Trauth et al. 1992) in several states, including Missouri. Several photographic reports from anglers capturing *C. a. alleganiensis* on trotlines during the winter in Missouri, especially the Gasconade River, have been received over the years (J. Briggler, pers. comm.). Based on these reports of *C. alleganiensis* being attracted to baited hooks, it seems plausible that baited traps could be an effective method of capturing *C. alleganiensis* in select Missouri rivers.

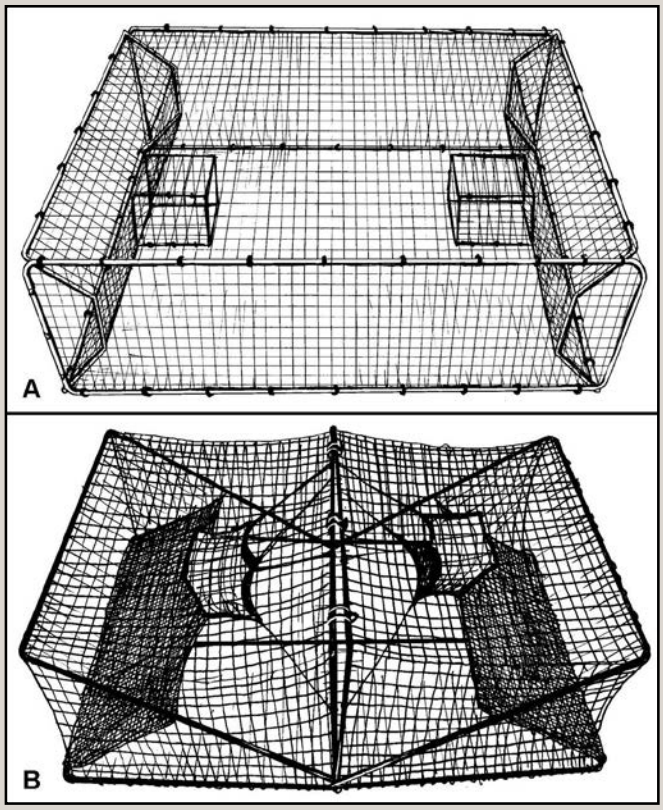

FIG. 1. Collapsible wire-mesh trap (A) and net-mesh trap (B) used to capture *Cryptobranchus a. alleganiensis* (Eastern Hellbender) in the Gasconade River, Missouri.

FIG. 2. Collapsible wire-mesh trap baited with *Dorosoma cepedianum* (Gizzard Shad) that captured two *Cryptobranchus a. alleganiensis* on 16 March 2009 in the Gasconade River, Missouri.

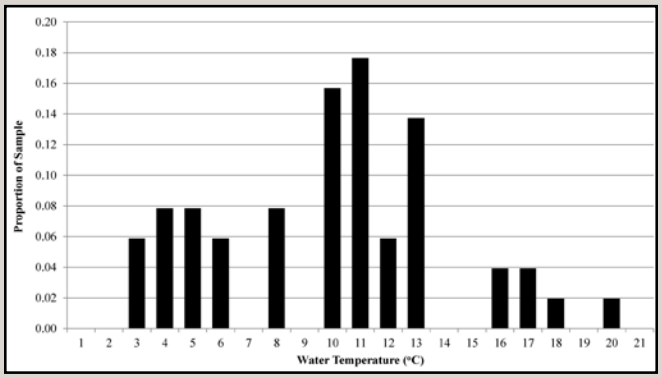

FIG. 3. Proportion of *Cryptobranchus a. alleganiensis* captured (N = 51) for the various water temperature (°C) from November 2007 through May 2009 in the Gasconade River, Missouri.

There have been several investigations that attempted to capture *C. a. alleganiensis* using baited traps with varying success (Foster et al. 2008; Kern 1984; Soule and Lindberg 1994). Soule and Lindberg (1994) baited wire-mesh traps with chicken livers with no success in New York. Kern (1984) used hoop-nets baited with cut sucker fish and captured 29 *C. a. alleganiensis* in Indiana. Foster et al. (2008) captured 22 individuals in New York drainages over 627 trap nights using plastic-coated hardware cloth traps baited with *Catostomus commersonii* (White Sucker). We are unaware of any previous attempts to sample deep, turbid habitat. Based on angler reports, some reported trapping success, and limited knowledge of sampling deeper water habitat, we decided to experiment with trapping design and trapping implementation to sample deep, turbid water habitat that was not conducive for other sampling techniques. The distribution and relative abundance of *C. a. alleganiensis* in these deep-water habitats is relatively unknown and likely to be important to the long-term recovery of the species. The objectives of this study were to 1) determine the distribution and relative abundance of *C. a. alleganiensis* on the lower sections of the Gasconade River, 2) examine the efficacy of baited traps to sample *C. a. alleganiensis* in deep, turbid water conditions, and 3) determine if trapping site characteristics influenced *C. a. alleganiensis* presence.

Materials and methods.—This study was conducted on the lower Gasconade River (7th order) in Gasconade, Maries, Osage, Phelps, and Pulaski counties, in Missouri. Water depths on the lower Gasconade River range from shallow riffles (< 0.5 m) to deep pools (> 8 m). Turbidity in the Gasconade River can be extremely high (Secchi depth < 0.5 m), especially during the summer as a result of algae blooms and sediment in the water. Water clarity does improve during the winter months but snorkeling and diving in cold, deep, flowing water is not recommended. With the aid of topographic maps and prior knowledge of *C. a. alleganiensis* habitat, sampling sites (N = 63) were identified along bluff banks over approximately 192 river km of the lower section of the Gasconade River. The substrates along these bluff banks are typically covered with large rocks suitable for *C. a. alleganiensis* occupancy.

Considerable trapping effort was conducted from February 2006 through August 2007 to evaluate bait types (*Dorosoma cepedianum*, *Hypophthalmichtys* sp., *Orconectes punctimanus*, crayfish magic bait, and chicken liver), distance between trap sets at a particular location, trap type (e.g., wire-mesh trap vs. mesh-net traps), trap design (two throats vs. one throat, collapsible vs. non-collapsible), trap set duration (24 vs. 48 h), and season of trapping (cooler vs. warmer weather months). Based on our experiences in 2006 and 2007, we decided to use custom-made collapsible wire-mesh traps and a few collapsible net-mesh traps. Collapsible traps allowed us to make efficient use of limited space in the boat and set a larger number of traps in a single day. We further decided on a 48-h trap set during the cooler months (November through early May) and to bait the traps with *D. cepedianum* (Gizzard Shad).

Trap design.—We used a wire-mesh and net-mesh trap design for this study. The wire-mesh trap was originally designed by

Foster et al. (2008), and we modified to include two throats and allow it be collapsible as outlined below. Both the wire-mesh trap and net-mesh trap consist of a rectangle design. The wire-mesh trap was made of 1.3 cm mesh green, plastic coated hardware cloth on a steel frame made from 9-gauge galvanized wire. The collapsible wire-mesh trap measured 61 cm long × 46 cm wide × 22 cm high with a funnel entrance on both ends measuring 7.5 cm high × 10 cm wide (Fig. 1a). Plastic zip ties were used to secure the funnel entrances (1 zip tie per entrance) and to hold the trap erect for setting (3–4 zip ties for each end). The collapsible net-mesh trap, also known as collapsible square fish trap, was purchased from Memphis Net and Twine (product code FTA). The net-mesh trap was made of 1.3-cm polyethylene mesh on a steel frame. This trap measured 60 cm long × 42 cm wide × 20 cm high. We modified the horizontal funnel entrance, converting it to a mesh funnel measuring 6 cm high × 10 cm wide on both ends of the trap, and we added 0.3-cm mesh netting to the base of the ramp leading to the funnel entrance to make the footing more firm for *C. a. alleganiensis* (Fig. 1b).

Trap deployment.—Trapping was conducted during the cooler weather months from November 2007 through May 2009 on the Gasconade River over 192 river km. During our first sampling period (November 2007 through May 2008), we aimed to trap monthly on the downstream 97 river km of the Gasconade River. February 2008 trapping was not conducted due to high river levels. Thirty-three unique sites were identified and 50 traps (40 wire-mesh traps and 10 net-mesh traps) were set monthly. Trapping was conducted at six sites in November, six sites in December, five sites in January, seven sites in March, four sites in April, and five sites in May. With the success during the first sampling period, we decided to conduct additional trapping in deep-water habitat further upstream. Our second sampling period occurred in November and December 2008 and March, April, and May 2009 at an additional 30 unique sampling sites scattered over 95 river km on the Gasconade River upstream of the sites sampled in the first sampling period. We decided to not trap during the coldest winter months of January and February, and constructed additional wire-mesh traps to increase sampling effort. Trapping was conducted at three sites in November, five sites in December, 14 sites in March, six sites in April, and two sites in May. We randomly set traps at unique sites in both upstream and downstream reaches for each month sampled during both sampling periods. We wanted to ensure equal chance of capturing animals among months due to limited historical records for *C. a. alleganiensis* from the most distant downstream reaches. No one site was trapped more than once during the course of this study.

Traps were only set along bluff bank sites that appeared suitable for *C. a. alleganiensis* occupancy; the sites contained large cover rocks (e.g., boulder, cobble, and slab rocks) with sufficient water velocity. The number of traps set per site varied on site length (i.e., longer sites had more traps) and ranged from five to 23 traps, and we randomly selected whether a wire-mesh or net-mesh trap was set. Traps were set from a boat due to the deep water conditions and often cold temperatures of the Gasconade River. Traps were secured by two means. First, a rope was secured to a tree or rock on the river bank (bank rope). The bank rope had a small loop (approximately 7.5–10 cm diameter) in the unsecured end. Next, the rope tied to the trap (anchor rope) was passed through the loop in the bank rope and secured to an anchor. The boat was then backed away from shore, and the anchor rope was then tossed upstream. As the boat floated downstream and slack in the anchor rope tightened, the trap was gently dropped in the water. Traps were scattered along the site length. A conscious effort was made to place each trap on a flat area of the river bottom adjacent to a large rock when water and weather conditions allowed. Traps were baited with a medium-size (approximately 14 cm), whole or cut shad (*D. cepedianum*) that was secured in a cloth mesh bag in the center of the trap. Secchi depth (m), water temperature (°C), and water velocity (m/sec) were measured at a representative spot at each unique sampling site, and photographs were taken of each location sampled. In addition, Global Positioning System (GPS) coordinates and water depth were recorded at each individual trap set location. Distance between traps (m) at a unique site was calculated from UTM coordinates. Length of site was distance between the most upstream and downstream trap. Trap setting was completed within eight hours each day, and traps were checked approximately 48 h later.

Each *C. a. alleganiensis* captured was measured for total length (TL), snout-to-vent length (SVL), and mass (g). Each *C. a. alleganiensis* captured was tagged in the dorsolateral musculature of the tail with a passive integrated transponder (PIT) tag. Photographs were taken of each *C. a. alleganiensis* captured. Each animal was released at the specific trap of capture after processing.

Capture efficiency was calculated as the number of *C. a. alleganiensis* captures per unit of effort (captures/trap and captures/trap night). Student's *t*-tests were used 1) to assess if trap parameters (depth of trap set, distance between traps) differed between individual traps with or without *C. a. alleganiensis*, and 2) to assess if site parameters (length of sampling site, water temperature, water flow, and Secchi depth) differed between sites with or without hellbenders. All sites and trap sets were independent because each unique site was only sampled once for the duration of this study. All statistical analyses were performed using JMP statistical software (SAS Institute, 2000).

Results.—Sixty-three river bluffs were trapped from November 2007 through May 2009 with *C. a. alleganiensis* captured at 31 (49.2%) of these sites. All *C. a. alleganiensis* captured were adults (N = 51) with an average (range) TL of 45.8 (40.0–51.0) cm, SVL of 30.4 (26.0–36.5) cm, and mass of 573 (360–981) g.

Monthly trapping during the first sampling period from November 2007 through May 2008 showed the highest captures for *C. a. alleganiensis* in April and November, while the highest captures in the second sampling period was March 2009 (Table 1). We captured a *C. a. alleganiensis* in each month, except for February, when we were unable to sample due to high river levels. During the pilot testing, however, we did capture a *C. a. alleganiensis* in February 2006.

Capture efficiency for *C. a. alleganiensis* was highly variable among sites, ranging from 0.02–0.14 captures/trap and 0.01–0.07 captures/trap night with March and April accounting for the highest capture rates (Table 1). Average capture efficiency for *C. a. alleganiensis* combining wire-mesh trap and net-mesh trap for both sampling periods was 0.073 captures/trap (1 individual/13.7 traps) and 0.036 captures/trap night (Table 1). Wire-mesh traps (0.079 captures/trap night) were almost twice as efficient at capturing *C. a. alleganiensis* as net-mesh traps (0.042 captures/trap night). On average, wire-mesh traps captured 1 *C. a. alleganiensis* per 12.6 traps compared to 1 *C. a. alleganiensis* per 23.6 traps for net-mesh traps. On four separate occasions, 2 *C. a. alleganiensis* were captured in one trap (Fig. 2) and in one trap a *C. a. alleganiensis* and *N. maculosus* were captured together.

TABLE 1. Capture efficiency, measured as number of captures/trap and number of captures/trap night, for *Cryptobranchus a. alleganiensis* (Eastern Hellbender) from November 2007 through May 2009 in the Gasconade River, Missouri. First sampling period was designed for monthly trapping. Second sampling period focused only on the months listed.

* Unable to trap in February 2008 due to high river levels.

TABLE 2. Site measurements for individual trap sets and individual trapping sites from November 2007 through May 2009 in the Gasconade River, Missouri.

Variables	N	Mean ± SD	Range	Hellbender presence ± SE	Hellbender absence ± SE
Depth of Trap Set (m)	698	1.8 ± 0.7	0.4-4.5	2.1 ± 0.09*	1.8 ± 0.03
Distance between Traps (m)	635	32.1 ± 18.2	1.4–114.0	30.3 ± 2.8	32.1 ± 0.8
Length of Sampling Sites (m)	63	485 ± 351	60–1,966	524.7 ± 65.4	451.7 ± 60.4
Water Temperature (°C)	63	10.4 ± 5.2	1.5–21.3	10.1 ± 1.0	10.7 ± 0.9
Water Flow (m/sec)	63	0.32 ± 0.22	0.01–0.93	0.27 ± 0.04	0.36 ± 0.04
Secchi Depth (m)	63	1.8 ± 0.8	0.5–3.4	2.1 ± 0.2	1.7 ± 0.1

*Indicates significant difference.

Mean, SD, and range of the site and trap-set parameters can be found in Table 2. Student's *t*-tests results found no significant patterns for distance between traps, length of sampling site, water temperature, water flow, and Secchi depth for the presence or absence of *C. a. alleganiensis* (Table 2). Although average water temperature at sites with and without *C. a. alleganiensis* was similar, 53% of captures occurred within a range of 10–13°C (Fig. 3). Traps with *C. a. alleganiensis* present were on average significantly deeper (t = -2.33, P = 0.02; Table 2).

Discussion.—Considerable information was gained regarding the distribution and relative abundance of *C. a. alleganiensis* in the Gasconade River, Missouri, through trapping in deep-water habitat along river bluffs that were not conducive to traditional snorkel diving methods. *Cryptobranchus a. alleganiensis*, a declining Missouri state endangered species (Briggler et al. 2007; NatureServe 2011), were detected at 31 undocumented sites with 51 individuals captured (Table 1). Wheeler et al. (2003) only captured 33 *C. a. alleganiensis* on the upper sections of the Gasconade River via snorkel diving. The deep water, river bluff sites we sampled may contribute significantly to the long-term persistence of this species in the Gasconade River. However, Wheeler et al. (2003) and our data show a lack of young age classes. We only captured adult *C. a. alleganiensis* estimated to be between 15 and 30 years of age (Taber et al. 1975). This lack of young age classes is likely due to the absence of these individuals in the population compared to historical sampling (Wheeler et al. 2003). Our trap mesh size was definitely narrow enough to capture small *C. a. alleganiensis*, and our traps did capture the smaller *N. maculosus* (TL range 22.5–31.0 cm). Additionally, trapping by Foster et al. (2008) captured mainly adult *C. a. alleganiensis* (> 40 cm TL), but 20% of captures were smaller animals even with the same mesh size as our study.

There have only been a few published accounts of researchers surveying *C. a. alleganiensis* via use of baited traps with varying success (Foster et al. 2008; Kern 1984; Soule and Lindberg 1994). Foster et al. (2008) was the first to report capture efficiency for *C. a. alleganiensis* by using wire traps. Our capture efficiency (ranging from 0.01–0.07 captures/trap night) was similar to Foster et al. (2008; ranging from 0.01–0.10 captures/trap night) and was highly variable among sites and among months (Table 1). The wire-mesh traps used in this study were of the same design and

size as Foster et al. (2008), but we modified the trap by making it collapsible and adding an entrance funnel at each end of the trap. The collapsible wire-mesh traps (1 capture/12.6 traps) were almost twice as efficient at capturing *C. a. alleganiensis* compared to collapsible net-mesh traps (1 capture/23.6 traps). It is unknown why *C. a. alleganiensis* would more likely be captured in the wire-mesh traps. It might be that the individuals can more easily escape the net-mesh trap, that the animals like the increased firm footing of the wire-mesh trap when entering the trap, or that the wire-mesh traps are more stable on the river bottom due to its heavier weight (wire-mesh traps = 2.08 kg compared to 0.91 kg for net-mesh traps). Even though the net-mesh trap can be purchased and modified accordingly with reduced labor cost, the significant increase in capture efficiency for the wire-mesh trap is definitely worth the effort to construct. Plus, the wire-mesh traps are more durable compared to the net-mesh traps; several of the net-mesh traps were damaged or destroyed by river debris.

Based upon reports of local anglers capturing *C. a. alleganiensis* in the winter on hook-and-line in the Gasconade River (JTB, pers. obs.) and our pilot data, we concluded that trapping during the cooler months was likely optimal for success. Trapping success was highest post-breeding of the species in November/December and again in March/April (Table 1). We were unsuccessful in capturing *C. a. alleganiensis* in the warmer months during our pilot testing on the Gasconade River unlike Foster et al.'s (2008) success in New York streams. In addition, we experimented with later spring and early summer trapping at sites known to support higher densities of *C. alleganiensis* on the Big Piney River and North Fork of the White River with no success. In Indiana, Kern (1984) showed seasonal variation in feeding activity with most *C. a. alleganiensis* containing food items in their stomach from January through April and very low percentage during summer and breeding season. This pattern is similar to what Peterson et al. (1989) observed in Missouri, and our ability to capture animals during the colder weather months. Also, high water conditions from January to May made sampling somewhat difficult and also might have influenced capture rates. November to mid-December might be the optimal time to sample due to more stable water levels and increase foraging due to post-breeding. An additional consideration, however, is that November is also a time when male *C. alleganiensis* are guarding nests.

There is no doubt that *C. a. alleganiensis* are attracted to baited traps based upon our success and the success of Foster et al. (2008), as well as the keen olfactory senses that *C. a. alleganiensis* are believed to possess (Gall and Mathis 2010; Nickerson and Mays 1973), but the majority of the diet reported for *C. a. alleganiensis* is primarily crayfish with occasional fish (Kern 1984; Nickerson and Mays 1973; Peterson et al. 1989). During our pilot data collection, we experimented with crayfish baits with no success. The lower Gasconade River appears to have lower numbers of crayfish compared to most other rivers inhabited by *C. a. alleganiensis* in Missouri (JTB, pers. obs.), and therefore, consumption of fish would be strongly related to availability compared to other prey items. *Cryptobranchus a. alleganiensis* captured during this study regurgitated native fish species on several occasions. Although *C. a. alleganiensis* have low metabolism and do not require frequent feeding (Nickerson and Krysko 2003; Nickerson and Mays 1973), limited preferred food resources in these deeper water habitats may contribute to trapping success because these animals are more likely forced to seek prey than to wait for prey to approach them.

Monthly captures may be influenced by food availability and/or reproductive season as discussed above, but water temperature likely plays an important role. The majority of the *C. a. alleganiensis* captures occurred at water temperatures < 14°C (Fig. 3). No *C. a. alleganiensis* were captured below 3°C or above 20°C. We believe that temperature likely affects trapping rates due to concerns such as decreased animal movements during extreme cold water temperatures and increase bait decay during warm water temperatures. Further investigations are needed to determine the role of water temperature, but we would recommend that trapping should not occur at water temperatures below 3°C or above 18°C and ideally between 8–16°C.

Cryptobranchus a. alleganiensis were significantly more likely to be captured in deeper trap sets in this study. Foster et al. (2008) showed that trapping appeared to be most successful at depths between 0.75 and 1.0 m; however, their study site was not as deep as the Gasconade River. Our data show *C. a. alleganiensis* were unlikely to be captured along shallow banks and in the deepest trap sets (> 4 m). These results are more likely an artifact of the preferred habitat of cover rock with the optimal river conditions (i.e., flow, water temperature, etc.) along these bluff banks than the actual depth of the water.

Compared to other sampling methods, trapping causes minimal habitat disturbance especially compared to turning rocks during snorkeling surveys (Browne et al. 2011; Foster et al. 2008). In addition, trapping is likely the most successful technique to use in deep water conditions, especially those affected by turbidity. Advantages to sampling in the colder months are that traps are less likely to be disturbed by river users (i.e., fewer individuals on river) and the by-catch mortality (e.g., turtles and fish) are almost nonexistent in colder water (Barko et al. 2004; Fratto et al. 2008). Trapping may not work for all river conditions throughout the range of the species since trapping success is likely influenced by stream characteristics (e.g., water depth, water temperature, etc.) food availability, *C. a. alleganiensis* density, and time of year (e.g., breeding). However, based upon our successes, trapping should be considered in larger, deeper, turbid rivers to locate additional populations of this declining species rangewide.

Acknowledgments.—A special thanks to A. Breisch for advice in the initial planning stages of this study, especially on the original trap design used by R. Foster. We also would like to thank T. Boersig, J. Calfee, W. Casner, A. Castillo, T. Grace, J. Girondo, J. Helming, J. Hoffman, K. Larson, A. Leary, D. Nolke, A. Rowden, W. Sexton, K. Singer, A. Tieben, R. Tilley, S. Voney, and A. Wright for assisting with field surveys. Thanks to L. Davis for data entry and editing, and M. Raithel for trap illustrations. Financial support for this project was provided by Missouri Department of Conservation. We complied with all applicable institutional animal care guidelines and state permit regulations.

Evaluating a Method for Non-destructively Obtaining Small Volumes of Blood from Gilled Amphibians

In many herpetological research projects, researchers incorporate measures of immunity, stress or other aspects of physiology that necessitate obtaining blood samples from their amphibian subjects. There are a number of proven techniques for sampling blood from amphibians (Baranowski-Smith and Smith 1983; Gentz 2007; Tapley et al. 2011; Thrall 2004), although some may only be useful with large species. For the smaller species (which have limited blood volume), the animals sometimes must be sacrificed. There are certain physiological measures though, that only require minor amounts of blood (less than 10 µl), such as investigations involving blood smear analysis, or molecular assays. For such projects, it would be beneficial to have a method for non-destructively obtaining blood so that the animals could be returned to their natal environment following the study, or so that more than one sample could be obtained from individual amphibians.

If larval or paedogenic salamanders are the subjects under study, it might be possible to obtain blood samples from their external gills, where blood flows continuously as part of normal respiration. In fact, such methods are already established for small fish (Watson et al. 1989); by making a minor incision in the gill filaments on one side of the animal, small amounts of blood can be siphoned with a microcapillary tube. The goal of the current project was to modify this same procedure for use with gilled amphibians, and evaluate its effectiveness for herpetological research. Here we report the results of an experiment where a collection of gilled salamanders (a paedogenic species) were sampled in the above manner, with and without anesthesia, to determine if the procedure affects survival in the days following the sampling.

Salamander collection and housing.—On 3 March 2011, we captured 34 aquatic, paedogenic Mole Salamanders (*Ambystoma talpoideum*), with dipnets from an impounded pond near the University of Georgia campus (Athens, Georgia, USA). This species is routinely used for studies in our lab (Davis and Maerz 2008a, b; Davis and Maerz 2010) and they are common

in northeast Georgia, especially in permanent water bodies. All salamanders were transported to the laboratory in a cooler of pond water, where they were placed individually into 1.9-L plastic containers filled with dechlorinated tap water and with one to two leaves (also collected from the source pond) for refugia. All containers were placed in an environment chamber that was set to a 12 h day length and at a constant temperature of 15°C. Salamanders were left in the chamber for 24 h before undergoing the blood sampling procedure (below).

Blood sampling.—Salamanders were randomly divided into three groups. Salamanders in Group 1 (N = 13) were first anesthetized via immersion in a solution of Orajel (20% benzocaine) following Cecala et al. (2007). Once immobile, each was blotted dry and weighed with an electronic balance, then lightly wrapped in a paper towel (to aid in handling), leaving the head and gills exposed. Then, using a sterilized pair of scissors, the distal end of one gill frond (Fig. 1) was cut off, and a heparinized microcapillary tube used to siphon the blood that welled from the severed gill. Salamanders in Group 2 (N = 13) underwent the same procedures (weighing, blood sampling), only without anesthesia. For salamanders in groups 1 and 2 we also noted the volume of blood obtained in the microcapillary tubes. The remaining salamanders (N = 8) were weighed and were subjected to the same degree of handling, but were not sampled. These salamanders served as a sham, or control group. All salamanders were returned to their respective containers (and placed in the environment chamber) following the processing and were monitored daily thereafter for four days. After four days, the salamanders were re-weighed, then released into their original pond.

Data analysis.—We first examined whether the volume of blood obtained with this procedure differed between anesthetized and non-anesthetized salamanders, using a Student's t-test. Next, we examined the degree of weight change for salamanders in each group using paired t-tests. Finally, we had intended to test for differences in survival rates across the three treatment groups, although there was no mortality in any group (below). Tests were performed using Statistica 6.1 software package (Statistica 2003).

Effects of the procedure.—No salamanders died in the experimental or the control groups during the four-day monitoring period. We also did not observe any atypical behavior in the salamanders that had been bled, during the post-procedure monitoring. The severed gills of experimental salamanders appeared to have healed by day 4, but we saw no evidence of regeneration. When we examined the change in weight from the day of bleeding to the last day, we found no significant weight change in either the Group 1 ($t = 1.22$, $df = 12$, $p = 0.243$) or Group 2 salamanders ($t = 0.311$, $df = 12$, $p = 0.760$). Collectively, these results all indicate that this blood-sampling procedure has minimal outward effects on salamanders.

Effectiveness of the procedure.—The average volume of blood obtained in both bleeding groups was 3.2 µl (standard deviation = 3.1 µl). Interestingly, we obtained significantly more blood from anesthetized salamanders than from non-anesthetized individuals ($t = -2.14$, $df = 24$, $p = 0.043$); the average for anesthetized salamanders was 4.4 µl while for non-anesthetized salamanders it was 1.9 µl. Part of this difference may stem from our inability to draw blood from one non-anesthetized salamander that thrashed during the procedure and made it difficult to place and hold the capillary tube on the gills. In fact, all non-anesthetized salamanders wiggled somewhat during the procedure, making it challenging (but not impossible) to siphon the blood. On the other hand, we cannot rule out the alternative possibility that more blood flowed from the anesthetized individuals because of some "relaxation" effect of the anesthesia on the animals' blood vessels.

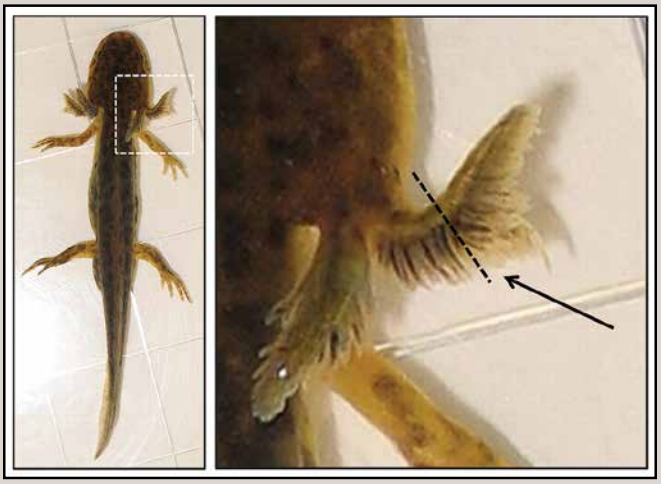

FIG. 1. Paedogenic *Ambystoma talpoideum* with close-up of gill filaments where blood was obtained. The distal tip of one filament (arrow) was severed with sterile scissors. Blood that welled from the cut was siphoned off with a heparinized microcapillary tube.

It is important to point out that the overall volume of blood yielded by this procedure (~5 µl or 0.005 g) would constitute less than 1% of the body weight of *A. talpoideum* (the average weight of *A. talpoideum* in this study was 3.0 g ± 0.6 g SD) and of other similarly-sized salamanders, which is a criterion recommended by Wright and Whitaker (2001). Similarly-sized species (with gills) would include paedogenic newts (family Salamandridae), paedogenic Tiger Salamanders (*A. tigrinum*), and Axolotls (*A. mexicanum*). Late-stage, gilled larvae of other species could also be used if they weighed more than 0.5 g.

The small amount of blood obtained may also limit the suitability of this technique for research purposes (because much larger volumes are needed for many clinical tests). Nevertheless, this volume would indeed be sufficient to conduct certain hematological investigations where only blood smears are needed (e.g., Davis and Maerz 2009; Davis and Maerz 2011; Davis and Milanovich 2010). With practice, it is possible to make (small) blood smears with this amount of blood (AKD, pers. obs.), which can be used to examine blood cells or search for intra- or extra-cellular parasites (e.g., Davis and Cecala 2010; Desser 2001; McAllister et al. 1993). Therefore, although the volume of blood obtained is small, this procedure appears to be useful for non-destructively collecting blood from gilled amphibians, and should serve a variety of purposes to researchers and herpetologists.

Acknowledgments.—We thank Sonia Altizer for allowing use of lab space for this project. All procedures in this project were approved by the University of Georgia's Animal Care and Use Committee (AUP # A2011 02-034-A1).

The Use of Photo-Identification as a Means of Identifying Western Painted Turtles (*Chrysemys picta bellii*) in Long-Term Demographic Studies

Critical to any successful long-term demographic study is the ability to accurately identify subjects during recapture events. Previous mark-recapture studies involving freshwater turtles have employed a number of various mutilation techniques such as toe clipping, notching of the shells, or the use of PIT tags. However, the use of mutilation techniques may present a potential risk to the turtles as notching or filing of the shell can cause fracture or lead to potential infections, particularly in hatchling and juvenile turtles (Cagle 1939). Additionally, there are ethical concerns when marking rare or endangered species. While the use of PIT tags can reduce the risk of injury, PIT tags cannot be used on hatchling or small juvenile turtles due to body size limitations (Buhlmann and Tuberville 1998).

The use of photo-identification to identify individuals offers several advantages over other methods in that it is less invasive, eliminates the risk of injury or infection, and can be used to accurately identify hatchlings and juveniles on subsequent recaptures. Further, a photographic data base could have long-term applications that could be shared among researchers. However, in order for photo-identification to be reliable, the meristic character used for identification must be unique to each individual and must remain relatively unchanged over time. For example, plastron pigmentation in Midland Painted Turtles (*Chysemys picta marginata*) has been shown to change in response to environmental variables such as substrate color (Rowe et al. 2006a, b, 2009). Juvenile pigmentation patterns may change as individuals mature, as in the case of plastron markings in juvenile Wood Turtles *Glyptemys insculpta* (Cowin and Cebek 2006). However, photo-identification has been successfully used to identify individuals in populations of Spotted Salamanders (*Ambystoma maculatum*, Loafman 1991), Daruma Pond Frogs (*Rana porosa brevipoda*, Kurashina et al. 2003), Leatherback Turtles (*Dermochelys coriacea*, McDonald et al. 1996), and Loggerhead Sea Turtles (*Caretta caretta*, Schofield et al. 2008). The plastron markings of some species of turtles are unique to individuals and as such may provide an accurate means of identifying individuals during demographic studies. Janzen et al. (2000a; 2000b) used plastron marking to successfully identify hatchling and juvenile Red-eared Sliders (*Trachemys scripta elegans*). More recently, Tichy and Kintrova (2010) demonstrated that plastron morphology could be used to accurately identify individuals in populations of European Tortoises *Testudo graeca ibera*. To date, the use of photo-identification to identify individuals has not been employed in any long-term demographic studies on Painted Turtles (*Chrysemys picta*). The Western Painted Turtle (*C. p. bellii*) possesses expansive and distinct plastron markings that make it an ideal candidate for the evaluation of photo-identification as an individual recognition technique. The goal of the present study was to determine if the use of plastron markings on *C. p. bellii* could provide a non-invasive method for accurately identifying

individuals during long-term demographic studies. To address this, we used both experienced field observers and untrained volunteers to identify individuals using initial and recapture photographs maintained in a photographic data base.

We captured and photographed 371 Western Painted Turtles from Chapman Lake in Durango, Colorado, USA, between April 1995 and August 2012. Each individual was assigned a unique ID number that was placed on the plastron with an adhesive label or a non-toxic, non-permanent marker that was later removed after photographing the plastron. Plastrons were photographed using a Canon 35mm SLR with a 52mm macro lens. Each plastron was photographed under natural lighting at a distance of 0.2–0.4 m depending on the size of the plastron in order to fill the entire field of view. Photographs were later scanned into digital format where they were cropped and edited for contrast using Adobe Lightroom (v 2.0). Plastron photographs were taken during every capture event and a catalog of 100 × 150 mm color prints was maintained for each individual.

To ensure accurate identification during recapture events and to verify that the plastron marks remained unchanged over time, it was necessary to use additional means to positively identify individuals during recaptures, such as notches filed in the marginal scutes, damaged or deformed shells, and carapace scute anomalies such as supernumerary scutes. Of the 371 turtles that were photographed from our study area, 15 turtles (seven males and eight females) had distinct physical features that allowed verification of identity in addition to the plastron markings.

We assessed the validity of photo-identification using three experienced field observers and 15 untrained volunteers. Experienced observers were trained on how to use photo-identification and had a minimum of 10 hours in the field using this technique. The untrained observers had no prior experience with painted turtles or the use of photo-identification. For each observer, we randomly selected a subset of 10 turtles from the set of all photographs (15 initial photographs and 65 recapture photographs). Age of turtles within each subset varied from 1–19 years (as estimated from growth annuli and original capture dates) and the time between the initial photograph and the subsequent recapture photograph varied from 3–16 years. Midline plastron length (PL) for turtles ranged from 52–214 mm. Photos that showed shell deformities or notches were not included in any of the subsets. Each observer was asked to identify the 10 turtles in the subset by matching a recapture photograph with the initial photograph from a set of 20 photographs, 10 of which contained turtles not included in the recapture subset. A new subset of photographs was used for each volunteer. Observers were not timed, but most were able to complete the task in less than 10 minutes.

The overall success rate for the three experienced field observers in correctly identifying individuals was 100%. The overall success rate for untrained observers was 95.3%. Nine of the untrained observers correctly identified all 10 turtles from recapture photographs. Of the remaining observers, five correctly identified nine out of 10 and one correctly identified eight of 10. Juveniles proved to be more difficult to identify as the pigmentation patterns are not as fully developed as in older individuals. However, our experience with this technique has indicated that distinct plastron markings of juvenile western painted turtles older than one year of age (one growth season) do not change over time and in fact, become more defined with age (Fig. 1). The overall success rate achieved in these trials suggests that photo-identification can be used reliably for this subspecies of painted turtle.

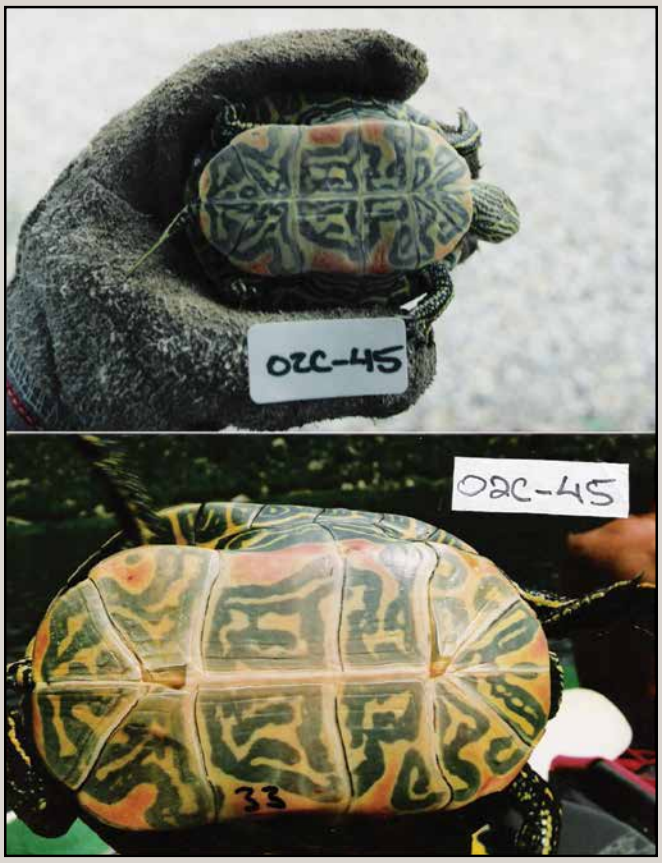

FIG. 1. Two-year old juvenile photographed on 1 August 2002 (top) and at subsequent recapture on 27 July 2007 (bottom).

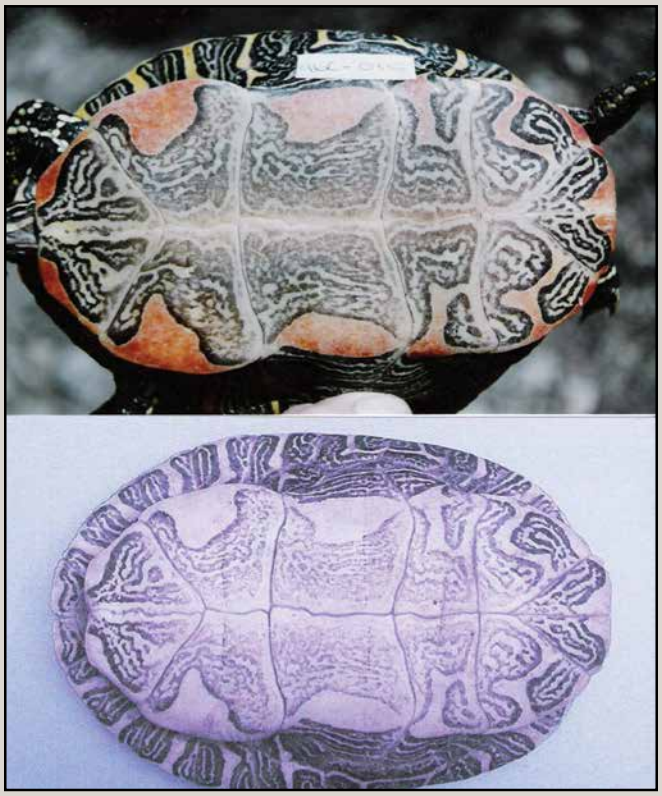

FIG. 2. Adult male photographed on 11 May 1996 (top) and upon found being dead on 26 May 2002 (bottom).

In one case, we were able to compare plastron markings on an individual that was marked in 1996 and had died sometime between 2001 and 2002 by matching the remains of the plastron with an earlier photograph. While the characteristic orange and yellow pigmentation had faded from the plastron, the distinct background markings remained, making identification possible (Fig. 2). We noted one potential problem when using this technique in late summer when the turtles were shedding their scutes: during this time the markings of the plastron became noticeably hazy and minute details of the plastron markings were sometimes obscured. Ideally, sampling events should be avoided during the shed cycle as the quality of photographs may be adversely affected.

Acknowledgments.—We are indebted to the Whitley family for allowing us to collect on their property. We also wish to thank T. Whitley and K. Cooley for their invaluable help in the field. All turtles were caught and released in accordance with the Colorado Department of Wildlife scientific collecting permits and all research protocols were conducted under the Colorado State University and Regis University IACUC guidelines.

Straight from the Ungulate's Mouth: A Technique for Protecting Data-loggers

The advent of passive acoustic monitoring has vastly improved our ability to collect data on wildlife species that vocalize. Studies that examine a wide variety of taxa have taken advantage of these data collection devices to answer questions of species presence, community diversity, and the effects of sound on wildlife (Goyette et al. 2011; Milne et al. 2004; Shearin et al. 2012). These systems have been used in a wide variety of conditions from arctic wetlands to arid deserts, to forested systems and even in urban settings. Each of these settings comes with its own problems and pitfalls. In this study, we describe some of the problems and solutions for protecting passive recording devices in rangeland systems lacking vertical structure.

We used passive recording devices in northeastern New Mexico, USA, to monitor amphibian communities in the southern High Plains, a semi-arid grassland dominated by agriculture and rangeland. In this region, ephemeral surface water is located in playa wetlands and stream drainages crossing the grasslands. Earthen cattle tanks and artificial impoundments associated with the river serve as permanent water sources.

Heavy monsoon rains are typical during the spring and summer in the plains, and amphibians residing here have developed an explosive-breeding style to take full advantage of novel breeding habitat. Because of the remoteness of the system and haphazardness of rain events, audio data loggers are useful in allowing us to sample amphibian breeding choruses when we are not available to conduct manual call surveys. These devices are typically attached to trees or other vertical surfaces; however, due to the lack of vertical structure in these grasslands we needed to attach the data loggers to posts. Deploying devices on the ground was not an option due to the risk of water damage from submergence during monsoon rains.

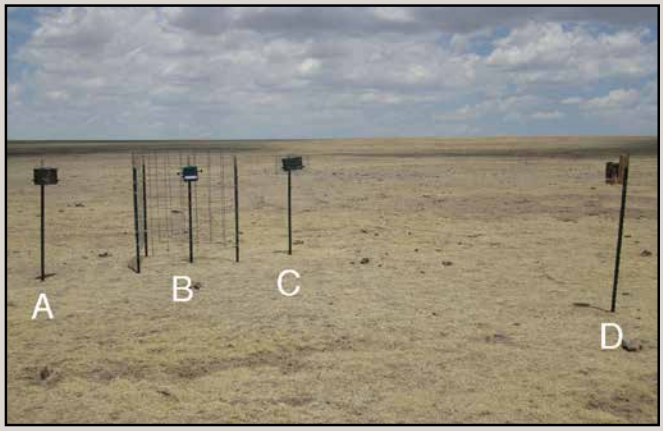

FIG. 1. Experimental design in New Mexico in 2011. A) Control, B) fence, and C) box treatments; D) game camera.

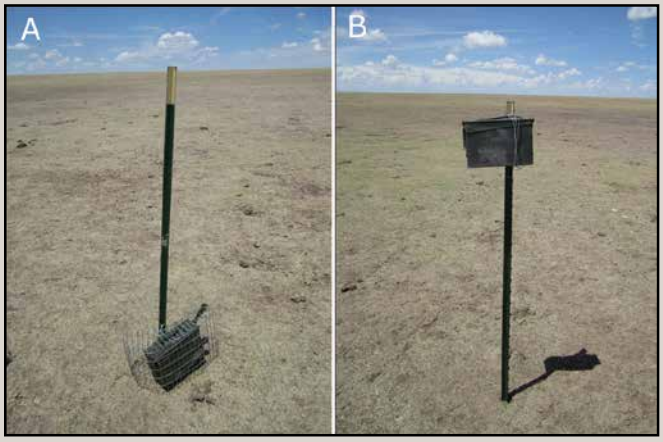

FIG. 2. Treatments after 7 days exposure to ungulates in New Mexico in 2011. A) Box treatment dislodged and the left microphone removed; B) control with both microphones removed.

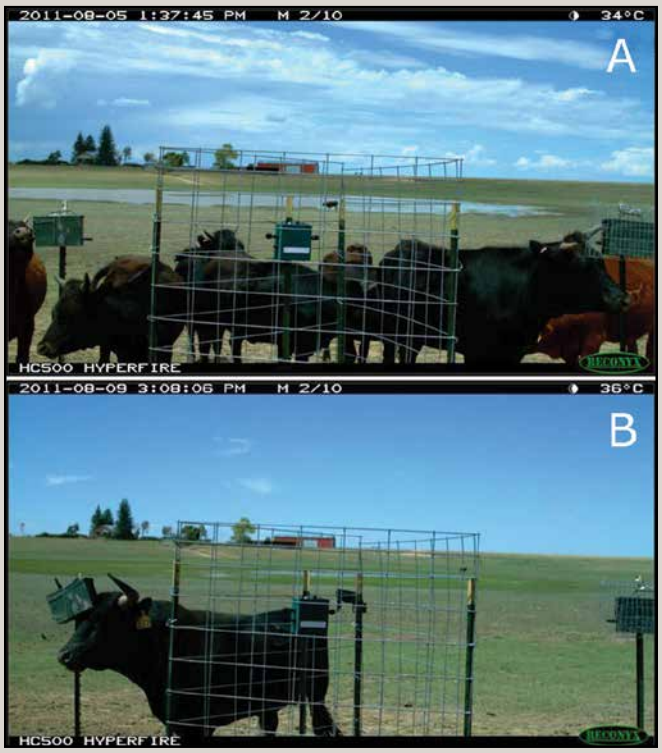

FIG. 3. Pictures from game cameras showing ungulates destroying devices in New Mexico in 2011. A) Cow consuming microphone of control treatment; B) cow rubbing on device and post of control treatment.

Ungulates can interfere with field equipment through several mechanisms. Researchers in various systems worldwide have had problems with these animals ingesting different types of plastic (Provenza 1996; Ramaswamy and Sharma 2010; KLG, unpubl. data, A. Berentsen pers. comm.). Ungulates also tend to rub against objects, and in landscapes such as the southern High Plains that lack vertical structure, they can significantly damage equipment secured to these structures.

During our initial use of the audio data loggers in 2011, we deployed 10 devices. We attached each device with screws to the top of two, 1.5-m wooden posts and placed them at different playa wetlands. After 7 days, 7 of the 10 devices had either had the microphones consumed or had the stand knocked down. This led us to design the following study, evaluating the degree of protection needed to guard the Wildlife Acoustics Song Meter SM2+ Recorder from ungulate depredation. This work will provide other researchers with suggestions for the level of protection needed in a grassland system.

Methods. —This study was conducted on privately owned rangeland in the southern High Plains in northeastern New Mexico during 2011. We evaluated the following treatments: control (no protection), box treatment (protection for the logger only), and fence treatment (protection for the logger and the post). Because the initial goal of the project was to evaluate amphibian breeding choruses, each device was deployed at the edge of a playa wetland. We had seven replicates (each with a different playa wetland and different landowner) with all three treatments represented within each replicate.

Because audio data loggers can be expensive, we created model devices by attaching foam balls with plastic stems (to simulate microphones) to either side of an ammunition box. In all treatments we attached the passive recording device with fencing wire to the top of a 1.8 m t-post. The control treatment (Fig. 1A) had no protection. To create the box treatment (Fig. 1B) we devised a rectangular exclosure (48.3 cm × 27.9 cm × 12.7 cm) out of mesh (5 cm × 2.5 cm) hardware cloth, placed it over the device, and secured the box using fencing wire. We created the fence treatment (Fig. 1C) by constructing a triangular fence, constructed from cattle panels (1.8 m long by 2.1 m tall) and 3 T-posts, around the data-logger. Cattle panels are rectangular sections of rigid welded fencing that do not need to be stretched between fence posts (Fig. 1, 2). These three treatments represent a continuum of physical and financial costs, from fewest to most resources needed.

We spaced the three treatments approximately 1 m apart next to the playa and positioned a motion sensitive game camera (HyperFire Semi Covert IR; Reconyx, Inc.; Holmen, Wisconsin) across from them (Fig. 1D), with all three treatments within its field of view. We left the treatments up for 7 days and upon returning, evaluated the damage by recording levels of destruction of the mock equipment. The protection was considered unsuccessful if either the microphones were destroyed/removed (Figs. 2a, 3a) or the audio data logger was dislodged from the post (Figs. 2b, 3b). We analyzed the data using a contingency table and Kendall's tau-b (Agresti 1990; SPSS 2011).

Results.—We found that the three exclosure types were significantly different from each other ($\tau = 12.6$, $p < 0.0005$) in their ability to protect equipment from ungulate damage. Specifically, we found that the fence exclosure protected the data-loggers in all replicates while 57% in the box treatments and 0% in the control treatments were protected.

Discussion.—Our study documented clear evidence that cattle fence exclosures are the most effective at protecting passive recording devices from ungulates when compared to box exclosures and no exclosures. Fence exclosures kept ungulates from rubbing against the post and protected the microphones from consumption. Others have used exclosures to protect young trees from browsing (e.g., Kota and Bartos 2010), but we have found no published literature on the protection of passive recording devices.

Fences provided the most protection for the passive recording devices for two reasons. First, a large amount of force can be applied to a triangular fence design without it being destroyed. Furthermore, the width and gauge of fencing we used provided strength, but flexibility. Second, the devices were placed within the fence, and were out of reach from ungulates. An added benefit of our fence treatment is its mobility and reusability. Each fence treatment was assembled by one person in 30 minutes, and disassembled in 10 minutes. We recommend this protection technique for studies requiring equipment placement in a conspicuous location where ungulates are present. We recommend the use of fences approximately 0.3 m taller than the shoulder height of tallest damage-prone ungulate in the region. Choosing the appropriate protection method for field equipment is generally constrained by time and funding; however, when using costly equipment such as passive recording devices, it is worth the extra expense to protect them in grassland systems.

Acknowledgments.—We thank New Mexico Game and Fish Share with Wildlife Program and the Department of Natural Resources Management at Texas Tech University for supporting this research. We also thank the volunteers on this project including R. Ramesh, L. Arvidson, J. Quigley, and M. McConnell, as well as the private landowners who graciously gave us permission to use their land and cattle. The Use of Gastric Transmitters to Locate Nests and Study Movement Patterns of Breeding Male Ozark Hellbenders (*Cryptobranchus alleganiensis bishopi*)

Hellbenders (*Cryptobranchus alleganiensis*) are large fully aquatic salamanders inhabiting rivers and streams of the eastern United States. Two subspecies occur in the Ozark Highlands of Missouri: the Ozark (*C. a. bishopi*) and Eastern Hellbender (*C. a. alleganiensis*). Throughout most of the year, Hellbenders are solitary animals moving among large rocks or bedrock crevices for foraging and shelter (Peterson and Wilkinson 1996; Smith 1907). However, during the breeding season (September–October), male Hellbenders establish nesting sites under specific rocks and aggressively defend nests from other males (Alexander 1927). Males occupying a nesting site guide females into the cavity in an attempt to secure a mating (Petranka 1998). Females deposit a clutch of 200 to > 400 eggs, and males fertilize the eggs externally (Nickerson and Mays 1973; Phillips and Humphries 2005; Smith 1907). After egg deposition, males chase the females out of the nesting cavity and actively guard the eggs and larvae (Petranka 1998).

Both subspecies of Hellbenders have experienced marked population declines in Missouri (Briggler et al. 2007; Wheeler et al. 2003) and are considered critically-imperiled and state-endangered (MONHP 2012). In November 2011, *C. a. bishopi* was added to the federal endangered species list (USFWS 2011).

Due to the severe population declines, there is a vital need to collect eggs from the wild for captive propagation efforts and use of young for research projects to address the decline. Although few nests have been found in the wild in Missouri (Dundee and Dundee 1965; Nickerson and Tohulka 1986; Unger and Mathis 2013), the nest-guarding behavior of male Hellbenders provides an ideal opportunity to track their movements as a technique to locate egg clutches.

Radio-telemetry is a technique widely used to monitor animal movements across a variety of taxonomic groups and habitat types. The study of movements and dispersal in small organisms such as salamanders has become more feasible given the technological advances in the size, weight, and battery life of transmitters. External and surgically-implanted internal transmitters have been used to track various species of salamanders including ambystomatids (Faccio 2003; Madison 1997; Madison and Farrand 1998; Rittenhouse and Semlitsch 2006; Steen et al. 2006; Trenham 2001), cryptobranchids (Ball 2001; Blais 1996; Bodinof et al. 2012; Burgmeier et al. 2011; Coatney 1982; Gates et al. 1985; Okada et al. 2006; Stouffer et al. 1983; Wheeler 2007; Zheng 2006), and salamandrids (Jehle and Arntzen 2000). Although data on the utility of gastric implant transmitters are more limited, they appear to be a useful tool for tracking salamander movements on a short-term basis (Blais 1996; Coatney 1982; Schabetsberger et al. 2004).

The purpose of this study was to use gastric implant transmitters to radio-track adult male Ozark Hellbenders (*C. a. bishopi*) during the breeding season to understand their movement patterns, but more importantly, to locate egg clutches in the wild. Gastric implants were selected over external or surgical implants due to the increased risk of impairment these latter attachment methods pose to the animals (i.e., anesthesia overdose, prolonged recovery, skin abrasions or tears, infection, or entanglement) and for ease of implantation at the study site.

Materials and methods.—Movements of adult male Ozark Hellbenders were tracked on the lower North Fork of the White River in southern Missouri from 28 September–8 November 2006 and 21 September–1 November 2007. The study site was a small 0.17-ha area of habitat characterized by shallow, moderately-flowing water, and a substrate comprised of numerous chunk rocks, boulders, and gravel. Animals were collected by turning suitable cover rocks, via snorkeling, and then replaced to their original position. Individual Hellbender locations were temporarily marked with numbered floats, and GPS coordinates, water depth, rock measurements (length, width, height), and substrate composition were recorded. A portable digital scale (Ohaus) and tape measure mounted in 10 cm diameter PVC pipe cut longitudinally in half were used to obtain mass (± 0.1 g), snout–vent length (SVL ± 0.5 cm), and total length (TL ± 0.5 cm) of each male, and PIT tags (Avid) were subcutaneously injected into the dorso-medial surface of the tail. Individual males are hereafter identified using the last three digits of their PIT tag number.

Gastric radio transmitters were purchased from Advanced Telemetry Systems (ATS Model F1010; Isanti, Minnesota) with a marketed battery life of 26 days. Transmitters measured 17 mm × 7 mm (length × diameter) and weighed 1.4 g. Transmitters emitted a pulsed signal with a frequency range of 164–165 MHz (pulse rate: 30 ppm; pulse width: 20 ms) (Table 1). To ensure that transmitters would safely pass through the digestive tract, we selected transmitter size based on the average size of undigested crayfish pinchers that are commonly excreted (pers. obs.). In all cases, transmitters comprised less than 0.6% of body mass (Table 2).

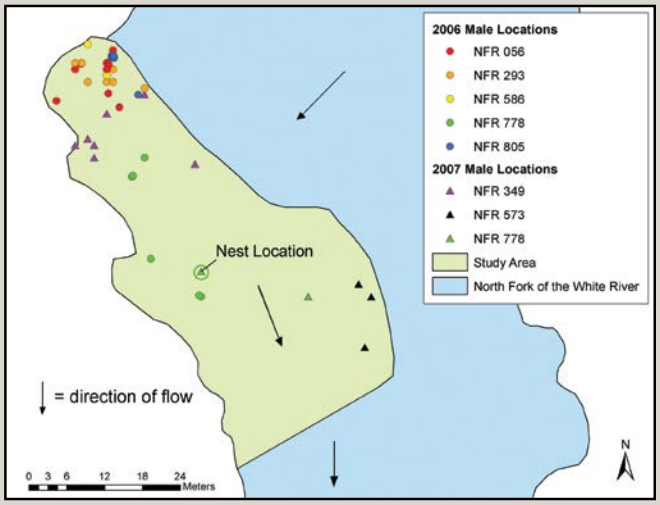

FIG. 1. Weekly locations of individual Ozark Hellbenders (*Cryptobranchus alleganiensis bishopi*) in the North Fork of the White River, 2006 and 2007.

TABLE 1. Transmitter specifications used in tracking male Ozark Hellbenders (*Cryptobranchus alleganiensis bishopi*) in 2006 and 2007 on the North Fork of the White River. Transmitters had a marketed battery life of 26 days, mass of 1.4 g, and frequency between 164.058 to 164.408 MHz. * Indicates individuals that received a second transmitter.

ID Number	Initial signal strength	Actual battery life (days)	Final signal strength

NFR 778	Moderate	19–26	None

Transmitters were coated with KY Jelly and inserted into a gel-coated disposable oral pill dispenser (11 mm diameter × 115 mm length; Four Paws, No. 01915). The mouth of an animal was gently prodded open using a thin, flat-tipped duckbill clip (Sally Beauty Supply). The pill dispenser was inserted approximately 4 cm into the esophagus and the plunger was depressed to release the transmitter into the esophageal cavity. The entire implantation process from opening the mouth to insertion of the transmitter took less than 10 seconds to complete. Males were then placed into plastic holding containers filled halfway with fresh stream water for a period of one hour to monitor for potential regurgitation of the transmitter, upon which they were returned to their exact capture location.

Seven male Hellbenders were captured on 28 September and 5 October 2006. Five males were selected for gastric implants, and the other two were deemed unsuitable due to small size and

TABLE 2. Morphological measurements of male Ozark Hellbenders (*Cryptobranchus alleganiensis bishopi*) on the North Fork of the White River. *Indicates individuals that received a second transmitter; 1.4 g was subtracted from their mass during the second implant to account for the mass of the first transmitter.

NFR 778	5	2	4.4	0.0	0.0–17.5

poor body condition (i.e., partial limbs with open lesions). The following year, four males were captured on 21 September 2007 of which three received transmitter implants. Because Ozark Hellbenders are critically imperiled, we opted not to increase our sample size until the safety of this technique was verified. Water depth at the study site was typically less than 1 m, but levels fluctuated by 0.5 m during 2006 due to several heavy rain events.

Hellbenders were radio-tracked during the day using either a Lotek (model STR1000) or ATS (model R2000) receiver in conjunction with a two-element folding Yagi antenna or an H-antenna (Telonics). Individuals were relocated one day post-implant to verify that the transmitters were not regurgitated, and then relocated approximately once per week thereafter. Once a transmitter position was located through triangulation, we visually confirmed the presence of the animal with an underwater camera or by carefully lifting the targeted rock. Starting the second week post-implant, each animal was captured to ensure that the transmitter was still retained. The status of the transmitter was recorded, i.e., retained within the animal, discarded (emitting a signal from outside the animal), or unknown (no longer emitting a signal) (Table 2). A GPS reading was also recorded for each location as were measurements of rock size, water depth, and type of substrate.

Locations for each individual were plotted using a Garmin GPS 76 in conjunction with aerial photographs to minimize error; UTM coordinates were adjusted according to known layout of habitat to reduce error to less than 1 m. To quantify movements, we calculated the linear distance between successive relocation points using the measure tool in ArcMap (version 9.1, ESRI Inc., Redlands, California).

Results.—A total of 10 gastric transmitters were implanted in seven individual male Ozark Hellbenders. In the first year, five males were implanted on 28 September and 5 October 2006; one of these males NFR 293 received a second transmitter on 9 October 2006 (Table 1). In the second year, three males were implanted with transmitters on 21 September 2007; one male (NFR 349) received a second transmitter on 10 October 2007 (Table 1). NFR 778 was the only individual implanted with a transmitter during both years of the study.

Mean TL of implanted animals was 39.1 ± 1.6 cm with a mean mass of 378.2 ± 44.8 g (mean ± SE, N = 8) (Table 2). On average, transmitter mass comprised only 0.4% of male body mass. No animals regurgitated the transmitter within the one hour post-implant observation period or discarded the transmitter for at least 13 days post-implant. The possible exception is NFR 586 which lost its transmitter signal within the first week of the study. Five of seven animals maintained the transmitter for a minimum of 19 days with NFR 293 retaining its transmitter over 30 days (Table 2).

During the study period, most of the Hellbenders utilized a small area of the available habitat (Fig. 1). In 2006, there was considerable overlap in habitat use compared to no overlap in 2007 (Fig. 1). Weekly relocations showed that males moved a median distance of 3.8 ± 1.0 m per week (mean ± SE, N = 8), and individual male movements ranged from 0.0–17.5 m per week (Table 3). Although movements were generally small, some males (e.g., NFR 056, 293, 349) moved among locations from week to week whereas other males remained mostly sedentary (e.g., NFR 805, NFR 778 in 2007). NFR 778 tended to move from location

TABLE 4. to location in 2006, whereas in 2007 this male only moved once from its initial capture location (Fig. 1; Table 3). The week after implantation, NFR 778 moved to the largest rock (surface area = 15,800 cm^2) used by any Hellbender in the study and stayed under this rock for the next four weeks. This male was found guarding a clutch of eggs on 17 October 2007.

There was considerable variation in rock size (length, width, and depth) used by male Hellbenders, with a mean rock length and width of 69.7 and 47.3 cm respectively (Table 4). However, we found no significant relationship between the size of males and the size of cover rocks (i.e., rock surface area) ($N = 8$, $R^2 = 0.09$, $p = 0.47$). Twenty-nine specific cover rocks and two bedrock crevices were used during the study. Although individual males were observed under the same rocks from week to week (Table 3), there was no overlap observed among males in rock selection during the study period.

Upon the conclusion of this study, three follow-up surveys were conducted between 2008 and 2010 to search for Hellbenders and egg clutches. While no concerted efforts were made to recapture the study animals, these surveys resulted in the recapture of five of the seven animals used in this study. Each animal had gained an average of 140 g. NFR 778 (used in both years of this study) gained 96 g between the 2006 and 2007 breeding season, and was recaptured in 2008 and 2009 where it had gained an additional 142 g.

Discussion.—Radio-telemetry has been used as a valuable tool to obtain information on movement, home range, and behavior in Hellbenders using a variety of different types of transmitter implants including coelomic, subcutaneous, gastric, and external (Ball 2001; Blais 1996; Bodinof et al.et al. 2012; Burgmeier et al. 2011; Coatney 1982; Gates et al. 1985; Wheeler 2007). Gastric implants have been shown to be a suitable method for assessing Hellbender movements on a short-term basis (Blais 1996; Coatney 1982), but the utility of this technique for locating egg clutches has not been previously investigated. Over the course of this study, we tracked seven individual males using gastric implants and determined that these transmitters are a practical, non-invasive method to locate nests and to learn information about male movement patterns during the breeding season.

The size, mass, and battery life of transmitters used in this study were suitable for our short-term tracking needs. Prior studies on Hellbenders indicated retention rates of gastric transmitters between 18-30 days (Coatney 1982) and 16-25 days (Blais 1996). In our study, males retained gastric implants for a minimum of 13 days to over 30 days with the exception of NFR 586 (Table 2). This male had a weak transmitter signal when relocated 24 h after implantation, and no signal could be detected during subsequent relocation attempts. Transmitter failure is a likely explanation for the loss of signal from this male; however, it is also possible the male migrated up- or downstream, was depredated, or was illegally collected from the study area. As of 2012, this animal has not been observed again despite extensive relocation efforts. We determined that a 26-day battery life

expectancy was sufficient for tracking Hellbenders during the active breeding period. While ATS transmitters were used in both years of this study, batteries lasted longer than the marketed 26-day life expectancy in year one, whereas performance was lower and more consistent with life expectancy in year two (Table 1). We also learned that a second gastric implant could be administered to extend tracking time; two animals (NFR 293 and 349) received a second implant with no observable harmful effect.

Transmitter size was selected based upon the size of crayfish pinchers and/or other chitinous parts that would pass through the digestive system of an adult Hellbender. Conversely, Schabetsberger et al. (2004) selected transmitters large enough that they would not pass through the digestive system and were forced to remain in the stomach. It is possible that Hellbenders could regurgitate our transmitters, but we attempted to select a size that was small enough to safely pass through the system without harming the animal (CCAC 2004; HACC 2004) and not so large that the animal would immediately attempt to regurgitate it. Further consideration needs to be taken into account when using gastric transmitters on Eastern Hellbenders which are larger than Ozark Hellbenders (Nickerson and Mays 1973). Blais (1996) implanted 5 g gastric transmitters (20 mm × 10 mm) in two Eastern Hellbenders and had similar retention rates as in our study, with transmitters being excreted after passing through the digestive system. While Blais (1996) did not provide any length data for these two individuals, the mass of his study animals ranged from 545–1318 g. General guidelines recommend that transmitters should be less than 5% of an animal's body mass for studies on amphibians and reptiles (ATS 2012). The Canadian Council on Animal Care and Use has adopted specific guidelines that suggest gastric transmitters not exceed 1% of an animal's body mass because they can alter behavior by mimicking food in the stomach (CCAC 2004). Therefore, mass and size of transmitters should be carefully considered when using gastric implants. Our transmitters were well within the recommended parameters (< 0.6% of body mass).

Only a few telemetry studies provide information on movements in wild Hellbenders (Ball 2001; Blais 1996; Burgmeier et al. 2011; Coatney 1982). Three of these studies either focused on short-term movements outside of the breeding season or on long-term seasonal movement patterns. However, Burgmeier et al. (2011) reported specifically on male movements during the active breeding season. Although our primary objective was not to address diel movements of male Hellbenders, our study does provide insight into movement patterns and habitat utilization during the breeding season. Our data for 2006 demonstrated considerable overlap in habitat used by five males, which is similar to results of other studies (Blais 1996; Coatney 1982; Peterson and Wilkinson 1996). Even though the areal extent of suitable habitat encompassed an area approximately 70 m in length by 25 m in width, four of the five males were clustered in a small 13 m × 14 m area during the entire 2006 study season (Fig. 1). Conversely, in 2007 the three tracked males utilized independent areas of habitat and showed little overlap (Fig. 1); however, we are unsure why this spatial pattern differed from 2006. Considerable variation in movement frequencies was observed among the animals in our study. Some individuals moved between rocks with greater frequency whereas others rarely moved and remained relatively stationary between weekly relocations (Table 3).

Hellbenders are known to use rock and bedrock crevice habitat for shelter and nest sites (Nickerson and Mays 1973; Nickerson and Tohulka 1986; Smith 1907). We found that Ozark Hellbenders utilized large rocks most frequently, and on two occasions, bedrock crevices as shelter sites. Individual males were often found under the same rock from week to week with an average of 3.6 rocks used per male (range: 2–9) during the breeding season. Previous studies reported similar variability in movement patterns and rock use in wild Hellbender populations (Ball 2001; Peterson and Wilkinson 1996). Peterson and Wilkinson (1996) found individual males on average utilized 6.3 cover rocks with a range of 1 to 13 rocks over a five month period from August to January. We would expect overall rock use (i.e., movement) in our study to be reduced since we targeted the breeding season when males are more sedentary. In Hellbenders it is rare to observe more than one individual under the same rock simultaneously (Hillis and Bellis 1971; Nickerson and Mays 1973; Peterson 1988); however, it is not uncommon for the same rock to serve as shelter for multiple animals over time (Peterson and Wilkinson 1996). In our study, male Hellbenders utilized 31 unique locations (i.e., 29 cover rocks and two bedrock crevices), but we never observed the same shelter site being utilized by more than one individual over the entire course of the study.

We conclude that the use of gastric implants is a practical technique for short-term studies of wild Hellbenders as previously demonstrated by Blais (1996) and Coatney (1982). But, more importantly, our study demonstrated the effectiveness of this technique in locating active nests. The importance of locating nests cannot be overstated since this endangered species has experienced marked population declines with larger, mature individuals predominating while small size classes are underrepresented (Briggler et al. 2007; Wheeler et al. 2003). The single egg clutch that we collected as a result of this study was incorporated into the long-term captive propagation efforts of the Ozark Hellbender. Gastric transmitters are quickly and easily implanted on site which reduces the stress and risk associated with surgical implant transmitters (i.e., off-site transportation, anesthesia, surgical procedure, extended recovery time, etc.). To achieve the goal of locating egg clutches, temporary removal (< 1.5 hours) of males from the river to implant gastric transmitters has less impact on their breeding behavior than other external or internal transmitter attachment methods. There has also been recent success using artificial nest boxes to augment nesting habitat, collect wild egg clutches, and propagate Hellbenders in captivity (Briggler and Ackerson 2012). However, the best technique to use in future studies will depend on factors such as stream morphology, water clarity, amount of suitable nesting habitat, and specific research objectives.

The long-term utility of this technique can be measured by the survivability and subsequent condition of the study animals. Coatney (1982) and Blais (1996) did not report adverse effects of gastric transmitters on Hellbenders on a short-term basis; however, they did not monitor animals for a long-term. In this study, five of the seven Hellbenders were recaptured in subsequent years and gained weight (mean =140 g gained). With at least 71% (5 of 7) survivorship and documented weight gains in subsequent years, gastric implant telemetry appears to be a useful, non-lethal tool for short-term studies in Ozark Hellbenders. This method may also have applications in short-term studies learning more about movement patterns and behavior of other imperiled species.

Acknowledgments.—We thank the Missouri Department of Conservation for logistics and funding of this project. We also thank J. Ackerson, C. Bodinof, J. Civiello, S. Crain, A. Crane, J. Kiger, J. Merkel,

A. Morgan, D. Mullich, A. J. Pratt, C. Schuette, A. Walker, and M. Wanner for providing field survey assistance with capturing and tracking animals. We give a special thanks to D. Madison and D. Blais for providing technical information and advice on transmitters. Research was conducted in compliance with applicable animal care guidelines, and appropriate permits were obtained from the Missouri Department of Conservation. Kelly Irwin and an anonymous reviewer provided helpful comments that improved the manuscript.

Visible Implant Alphanumeric Tag Retention in Green Frog (*Lithobates clamitans*) Tadpoles

Marking tadpoles is challenging. Traditional methods include fin-clipping and staining with neutral dye (Donnelly et al. 1994). More recently, researchers have trialed visible implant elastomers (VIE) and coded wire tags (CWT) as techniques to mark tadpoles (Anholt et al. 1998; Grant 2008; Martin 2011). The drawback to fin-clipping and staining is that their use is largely restricted to batch marking (e.g., dates or cohorts), rather than unique identification (Donnelly et al. 1994). Additionally, staining may affect the behavior of marked tadpoles (Carlson and Langkilde 2013), and the effect of fin-clipping on behavior or survival is unknown. VIE may be problematic because marks often migrate away from the marking site, are lost, or are read incorrectly (Bailey 2004; Grant 2008). CWT also has a high rate of tag loss (Martin 2011). Visible implant alphanumeric tags (VIAlpha tags, Northwest Marine Technology Inc., Shaw Island, WA) have the potential to solve these problems. VIAlpha tags are soft, biocompatible, fluorescent tags with a unique alphanumeric code printed on one side. Thus, they represent a promising approach to uniquely identify individuals. They have been used for marking a number of taxa including fish (*Oncorhynchus mykiss*, Isely et al. 2004; *Gadus morhua*, Olsen et al. 2004), crayfish (*Procambarus clarkia*, Isely and Stockett 2001; *Cherax destructor*, Jerry et al. 2001), lobsters (*Jasus edwardsii*, Woods and James 2003), and seahorses (*Hippocampus abdominalis*, Woods 2005). VIAlpha tags have also been used to successfully mark adult anurans (Ackleh et al. 2010; Buchan et al. 2005; Chelgren et al. 2006; Heard et al. 2008), caecilians (Measey et al. 2001; 2003), and salamanders (Osbourn et al. 2011). To date their use in marking tadpoles has not been tested, and this study is the first to report on tag retention in a larval anuran, the Green Frog (*Lithobates clamitans*). Our objective was to assess VIAlpha tag retention in this species.

Materials and methods.—As part of a larger study examining the reproductive success of amphibians inhabiting created wetlands (in which unique identification and mass of individuals were required), in March 2010 we collected 110 green frog tadpoles from a pool connected to a wetland in Grant County, West Virginia (39.2125°N, 79.42361°W). All individuals had hatched the previous summer and overwintered in the pool and were of similar developmental stage (Gosner stage 30–33; Gosner 1960).

We transported tadpoles to the laboratory where they were housed in 33 aquaria (~3 L plastic containers), with five tadpoles per aquarium. We maintained aquaria on a 14 h light: 10 h dark photoperiod at about 22°C. We fed a consistent amount of food (3:1 mixture of rabbit chow and flake fish food, Skelly 1994) to tadpoles once every other day. In an attempt to achieve a balance between disturbance to tadpoles and maintaining conditions as natural as possible, we did not aerate tanks and limited water changes to 1/3 of the water volume once a week with water collected from wetlands. As water was siphoned during water changes, we vacuumed uneaten food, feces, and debris from the bottom of tanks. We randomly assigned aquaria to spaces along a 9 m-long bench and randomly allocated individual tadpoles to aquaria.

Tadpoles were anesthetized in buffered 440 mg/L tricaine methylsulfonate (MS-222), placed on a water-saturated piece of soft foam and tagged using an injector specifically designed to accommodate the 1.2 mm × 2.7 mm VIAlpha tags (Fig. 1). We injected the tags by piercing the first layer of skin at the midpoint of the tail with the pointed injector tip and sliding the injector parallel to the skin towards the base of the tail above the muscle (Anholt et al. 1998). The tip of the injector was rinsed with clean water after each use (although rinsing with ethanol may be more appropriate to prevent disease transmission). We placed all tags on the left side of the tail fin, and care was taken to ensure that tag placement was consistent. Tadpoles recovered (until they resumed normal behavior, 2–5 minutes) in a container of clean distilled water before being placed into aquaria. We monitored tadpoles for tag retention daily until they either died or metamorphosed (mean 14 weeks, range: 1–80 weeks). To minimize disease risk associated with reintroducing amphibians into the wild, all metamorphs were euthanized in a 2% solution of MS-222.

Results.—VIAlpha tag retention was poor, with 25% of the tags lost in the first week (21% were lost in <24 h) and 82% lost within the first two weeks of the experiment. Four tags were not lost: three tadpoles died and one metamorphosed with tags still implanted. The remaining tags were lost by week 11 (day 75) for a total percentage loss of 96% (Fig. 2). No signs of infection, redness or swelling were present at the location of the incision, and marked tadpoles appeared to behave normally.

Discussion.—Contrary to many other taxa that have been marked with this method, VIAlpha tag retention in Green Frog tadpoles was poor. We believe that tag loss is most likely due to the nature of tadpole anatomy. Tags were initially secure in the tail because they were kept against the skin by the support of the tail myotomes. However, tail movement gradually pushed the tags posteriorly toward the skin incision where they exited the body and were lost (this took < 24 h in 23 individuals). Before the initiation of the experiment, additional tadpoles were used to identify alternative tagging locations; attempted locations included the belly, dorsum, and the cheek just beneath the eye. These locations could not be used because substantial subcutaneous musculature is minimal or absent; the tags immediately slid out of place or disappeared under layers of skin. In some instances, particularly on the dorsum, the tags would appear secure but were occluded by dark pigmentation and were not visible even when viewed with the deep violet wavelength light. This occlusion occurred on several experimental tadpoles as well, due to extensive pigmentation on the tail of some individuals.

Tag retention was much poorer in our study compared to two recent studies that used similar techniques. Grant (2008) used

visual implant elastomer (VIE) to mark larval Wood Frogs (*Lithobates sylvaticus*) and Martin (2011) used coded wire tags (CWT) to mark larval Mexican Spadefoot Toads (*Spea multiplicata*). Implantation of VIE is done with a small hypodermic needle (4 µm), and the liquid elastomer fills the cavity and then cures into a solid, most likely reducing the probability of loss through the small incision created by the needle. In contrast, the injector for the VIAlpha tags is relatively large (19 µm) and shaped identically to the tag, which probably makes loss of the 12-µm tag through the large incision more likely. Grant (2008) injected tadpoles in the same body location as in the present study and, although still too high for most mark-recapture studies, observed a tag loss of only 50% of one of two marks after 20 days, with no tadpole losing both marks. Martin (2011) injected CWT into the ventral tail fin of tadpoles and had a retention rate of 80% after eight days. We did not attempt tagging in the ventral fin, but CWT uses an injector that is small, similar to the VIE needle, and it may be that smaller incisions are less prone to tag loss than the larger incision created with VIAlpha tags, regardless of tagging location. It would be interesting to determine if CWT tag retention remains high over a longer time period.

We have identified two potential solutions that may improve retention in the future and thus render VIAlpha tags effective for individually marking tadpoles. First, closing the incision site with instant glue such as cyanoacrylate has been used in other studies involving aquatic amphibians (Heard et al. 2008; Reh and Constantine-Paton 1984), and it may prevent tag loss in tadpoles; however, this method is not completely effective (Heard et al. 2008) and its efficacy in submerged conditions is unknown. Second, Chelgren et al. (2006) described their procedure for marking adult Northern Red-legged Frogs (*Rana aurora*) with VIAlpha tags in which upon injection into the dorsum of the thigh they pushed the tag to a position on the ventral side of the thigh, away from the site of incision. Pushing the tag from the dorsum of the tail on tadpoles laterally to the side of the tail may significantly increase retention. This solution needs testing to determine its efficacy because the tail is frequently in motion and may expel tags regardless of position. Refining the application of VIAlpha tags with these potential solutions might yield an effective method whenever identification of individual tadpoles is required. We recommend more work to assess tag retention with protocol modifications and to determine the effect of VIAlpha tags on tadpole survival and behavior.

Acknowledgments.—We thank A. M. J. Anderson, G. Albers, and D. Hartman for help in the field and laboratory. Funding and logistical support was provided by the WVU Division of Forestry and Natural Resources through the McIntire-Stennis program, the WVU Environmental Research Center, and the National Oceanic and Atmospheric Administration. We received approval from the West Virginia University (WVU) Institutional Animal Care and Use Committee (#08-1001) to handle tadpoles and a scientific collecting permit was obtained from the West Virginia Division of Natural Resources (#2009.006) to collect amphibians. This is scientific article number 3167 of the WVU Agriculture and Forestry Experiment Station.

Escape Rates of Semi-aquatic Turtles from Basking and Funnel Traps

Traps used to sample animal populations or communities may be biased with respect to the probability of capturing particular subsets of species or individuals (Willson et al. 2008). For example, capture probabilities may differ between the sexes for specific trap types or during different portions of the active season (Noyce et al. 2001; Thomas et al. 1999). Likewise, the efficacy of some traps may vary across different habitats (Lambert et al. 2005; Ryberg and Cathey 2004). Biased sampling methods may produce inaccurate estimates of community or population-level parameters, hampering the development of management and conservation policies. Therefore, it is important to investigate the potential biases associated with methods used to sample animal populations and communities (Willson et al. 2008).

Some turtle traps are more likely to capture certain species, sexes, or sizes (Bluett et al. 2011; Browne and Hecnar 2005; Cagle and Chaney 1950; Fidenci 2005; Ream and Ream 1966; Sterrett et al. 2010). Basking traps take advantage of the basking habit of some turtle species (Boyer 1965) and usually consist of a basking platform (sometimes with treadles) mounted over a net or holding pen (Plummer 1979). Turtles are captured after diving or falling off of the basking platform. Basking traps are used to successfully capture species that commonly exhibit aerial-basking behaviors (e.g., *Trachemys scripta*; Gamble 2006; Thomas et al. 1999), but are unlikely to catch species that do not commonly engage in such behaviors (e.g., *Macrochelys temminckii*; Lagler 1943). In addition, some basking traps are more likely to catch large females than other individuals within a population (Ream and Ream 1966). However, the sexual biases of basking trap captures may vary seasonally (Thomas et al. 1999). The design of some basking traps may allow some turtles to escape from the holding pen (R. B. Thomas, pers. observ.). Gamble (2006) mentioned the possibility that escape rates from basking traps may vary for turtles of different sizes. However, no published studies have compared escape rates of turtles from basking traps.

Baited funnel traps are commonly used to sample freshwater turtle populations and communities (Gibbons and Greene 1990; Plummer 1979; Ream and Ream 1966). Bait (usually food) is used to motivate turtles to enter these traps through an inverted-funnel entrance. The ability of some turtles to escape from funnel traps has been documented (Brown et al. 2011; Frazer et al. 1990; Gamble 2006; Mali et al. 2013). Frazer et al. (1990) found that female *Chrysemys picta* often escaped from funnel traps, with 16 of 20 escaping during a 24-h period. In contrast, Brown et al. (2011) investigated the escape rates of *T. scripta* from funnel traps and found a negligible rate of escape (only 5 out of 139 *T. scripta* escaped within 34 h). Similarly, Mali et al. (2013) reported that only 8 of 107 *Apalone spinifera emoryi* escaped from funnel traps. Possible explanations for the disparity of results among these studies have not been explored. Differential escape rates between sexes or sizes could bias a sample and negatively impact estimates of population-level parameters. We examined the escape frequency of *C. picta* and *T. scripta* from basking traps and funnel traps. Specifically, we compared escape rates among males, females, and juveniles and examined the influence of body size on escape rates for both species.

Methods and Materials. We trapped turtles using funnel traps and basking traps from nine ponds in Lyon County, Kansas, USA, from 8 June to 26 September 2010. Traps were constructed with three rectangular 65 × 90 cm frames covered in 3.8-cm treated nylon mesh (Nichols Net and Twine, Inc., Granite City, Illinois); each trap had a single opening with a mouth height (the maximum vertical height of the inner opening of the funnel entrance; see Brown et al. 2011) that ranged between 10 and 15 cm (mean ± SD = 11.5 ± 1.5). We baited each funnel trap with canned mackerel held in a perforated PVC tube to prevent bait consumption (Nall and Thomas 2009); bait was changed every two days. Basking traps consisted of a 60 × 60 cm wood and Styrofoam frame with a 90-cm deep net basket underneath (Memphis Net and

JENNIFER M. SINGLETON*

R. BRENT THOMAS
Department of Biological Sciences, Emporia State University, Emporia, Kansas 66801, USA

**Corresponding author; e-mail: j.singleton@live.com*

Twine Co., Inc., Memphis, Tennessee). The frame supported a board set on a treadle suspended above a net. Long nails (~10 cm) driven through additional pieces of PVC tubing were then snapped onto the sides of the trap at ~20-cm intervals with the sharp end of the nails protruded over the inside of the trap at a 45°-angle from the water surface.

All turtles were uniquely marked for identification (Cagle 1939) and sex, species, and plastron length (PL) were recorded. Both Painted Turtles (*Chrysemys picta*) and Pond Sliders (*Trachemys scripta*) served as test animals in this study. Sex was determined using a combination of PL and the presence or absence of male secondary sexual characteristics. Turtles were considered adult males if they had elongated foreclaws, cloacae positioned posterior to the rear carapace margins, and PL >110 mm for *T. scripta* or >90 mm for *C. picta*; turtles with relatively short foreclaws, cloacae positioned near or anterior to the rear carapace margins, and PL >160 mm for *T. scripta* or >120 mm for *C. picta* were considered adult females (Gibbons and Greene 1990; House et al. 2010). Individuals smaller than these specified sizes that lacked these secondary sex characters were categorized as juveniles.

Captured individuals (both *C. picta* and *T. scripta*) were returned (at random) to either funnel traps or basking traps in their pond of capture. Traps were checked the next day and any of these animals found in the trap ~24 h later were recorded as "non-escapees," while those missing were assumed to have "escaped." Individuals were used as a test animal only once during these trials.

We tested escape frequency from basking traps with 77 turtles: 49 *C. picta* (22 males, 14 females, and 13 juveniles) and 28 *T. scripta* (11 males, 12 females, and 5 juveniles). We tested escape frequency from funnel traps with 88 turtles: 49 *C. picta* (23 males, 16 females, and 10 juveniles) and 39 *T. scripta* (11 males, 18 females, and 10 juveniles).

Male, female, and juvenile escape rates were compared using a Fisher exact test (Zar 2009). The likelihood-of-escape correlation with plastron length was analyzed using a Wilcoxon signed-rank test (Zar 2009). Level of significance was set at 0.05 for all statistical tests.

Results.—Overall, 74% of all turtles escaped from basking traps or funnel traps within 24 h. *Chrysemys picta* escaped from basking traps in 56% of trials (55% of males, 86% of females, and 31% of juveniles; Table 1). We observed significant differences among the escape rates of males, females, and juveniles (χ^2_2 = 9.07; P = 0.011). Juvenile *C. picta* escaped from the basking traps significantly less frequently than adult males or females. Mean PL of escapees and non-escapees were 133.9 mm and 106.0 mm, respectively. We found a significant difference in mean PL between escapees (133.9 mm) and non-escapees (106.0 mm; Z_1 = –3.21; P = 0.0013).

Trachemys scripta escaped from basking traps in 86% of trials (82% of males, 100% of females, and 60% of juveniles; Table 1). We did not observe a statistically significant difference among the escape rates of males, females, and juveniles, although our results approached significance (χ^2_2 = 5.80; P = 0.055); the low numbers in certain cells may have diminished the precision of the test statistic (Zar 2009). However, juvenile *T. scripta* were 40% less likely to escape than adult females. Mean PL of escapees (185.1 mm) and non-escapees (107.0 mm) was significantly different (Z_1 = –2.79; df = 1; P = 0.0052).

TABLE 1. Escape rates of *Chrysemys picta* and *Trachemys scripta* from basking traps over 24-h periods, 8 June to 26 September 2010 in Lyon County, Kansas, USA.

	Chrysemys picta				*Trachemys scripta*			
	Male	Female	Juvenile	Total	Male	Female	Juvenile	Total
Escapees	12	12	4	28	9	12	3	24
Non-escapees	10	2	9	21	2	0	2	4
% Escaped	55	86	31	56	82	100	60	86

TABLE 2. Escape rates of *Chrysemys picta* and *Trachemys scripta* from funnel traps over 24-h periods, 8 June to 26 September 2010 in Lyon County, Kansas, USA.

	Chrysemys picta				*Trachemys scripta*			
	Male	Female	Juvenile	Total	Male	Female	Juvenile	Total
Escapees	16	11	9	36	10	14	8	32
Non-escapees	7	5	1	13	1	4	2	7
% escaped	70	65	90	74	91	72	80	82

Chrysemys picta escaped funnel traps in 74% of trials (70% of males, 65% of females, and 90% of juveniles; Table 2). Differences in escape rates among these groups were not significant (χ^2_2 = 2.05; P = 0.36). The Wilcoxon signed-rank test comparing escapee and non-escapee PL showed no significant difference in escape rates by body size for *C. picta* (Z_1 = 1.44; P = 0.15; means 116.7 mm for escapees and 133.3 mm for non-escapees).

Trachemys scripta escaped funnel traps in 82% of trials (91% of males, 72% of females, and 80% of juveniles; Table 2). Differences in escape rates among these groups were not significant (χ^2_2 = 0.92; P = 0.63). The difference in mean PL of *T. scripta* categorized as escapees (171.2 mm) and non-escapees (159.7 mm) was not significant (Z_1 = –0.49; P = 0.62).

We investigated whether the incidence of escape in turtles was affected by their previous trap experience; for this purpose, we compared escape rates in a subset of first-time captures and experienced turtles (i.e., recaptured turtles). We compared the trap-experience of 69 escapee turtles and 20 non-escapees using Fisher's exact test. Trap experience and escape were independent (χ^2 = 0.66; P = 0.58).

Discussion.—Overall escape rates of turtles were greater than expected. Smaller *C. picta* and *T. scripta* were significantly less likely to escape from basking traps while large females of both species frequently escaped from the basking traps. Therefore, the use of basking traps to sample populations of these two species may result in an underrepresentation of large adults (particularly females).

Escape from funnel traps was relatively frequent; however, relative to basking traps, these traps were less biased with respect to differential rates of escape among males, females, and juveniles. Our results for *C. picta* escape from funnel traps (74%) were very similar to those reported by Frazer et al. (1990; 75%). In contrast, Brown et al. (2011) reported a negligible escape rate (3.6%) of *T. scripta* from funnel traps, versus 82% in our study. It is possible that differences in trapping methods or trap types could be responsible for the disparity among these studies. Our traps were constructed with rectangular 60 × 90 cm frames, while

Brown et al. (2011) used circular 76.2-cm diameter frames. The specific design and dimensions of the traps used by Frazer et al. (1990) were not reported. Perhaps different shapes and sizes of these traps were relevant to the different rates of escape. Specifically, our traps had a mouth height considerably larger (mean = 11.5 cm) than the mouth height of those used by Brown et al. (1.27–2.03 cm); the opening in our traps may have been easier to find and subsequently use for escape. Frazer et al. (1990) also used *C. picta* from a long-term study population of turtles and some of their study animals may have had extensive prior experience in funnel traps. Conversely, Brown et al. (2011) used *T. scripta* that were unmarked and presumably had not been trapped before. Our study used a combination of both "new" turtles and turtles that had been caught and marked previously and we found no difference in escape based on prior trap knowledge. Frazer et al. (1990) reported results similar to ours: 75% escape rate for female *C. picta* in 24 h. These studies also involved two species from three widely spaced study sites (Michigan, Kansas, and Texas) and the potential for geographic variation cannot be dismissed.

Future research should examine possible differences in turtle escape frequency among variations of funnel trap design (one-throated vs. two-throated, round vs. rectangular, etc.). In addition, the possible influence of the frequency of checking traps has not been investigated; Brown et al. (2011) found that all of the turtles who escaped did so in <27 h. Some researchers believe that checking traps more often than once per 48 h disturbs the site and reduces trap yield; others prefer to check their traps every 6–12 h (Cagle and Chaney 1950; Fidenci 2005; Lagler 1943). However, there have been no formal studies conducted to support or negate the efficacy of these practices.

We can conclude that *T. scripta* and *C. picta* have a great potential for escape from some forms of basking and funnel traps and that escape from these basking traps, in some cases, is biased by size. The trap types used for this research were only two of a variety of many different trap designs (Cagle and Chaney 1950; Fratto et al. 2008; Kennett 1992; Lagler 1943; Ream and Ream 1966) that may yield different results with similar testing. Researchers would benefit from an examination of their own trap types and potential escape bias. Of the two traps compared in this study, funnel traps yielded less biased samples of *C. picta* and *T. scripta* in these ponds.

Acknowledgments.—We thank Tommy Sterling and Skyler Delmott for their help and companionship in the field. We are grateful to the David Traylor Zoo of Emporia and local landowners for access to their properties. We thank David Edds, Lynette Sievert, and Larry Scott for their advice and contributions to this manuscript. We also give special thanks to Emporia State University for a Faculty Research & Creativity Grant and Graduate Student Research Grants to support this project. All collection took place under Kansas Department of Wildlife & Parks permit# SC-120-2010 and with approval from the ESU Animal Care and Use Committee (Protocol -10-011).

Color Recognition as a Management Tool with a Female Nile Crocodile (*Crocodylus niloticus*) at the Wildlife Conservation Society's Bronx Zoo

Animal sensory systems are the product of environmental and evolutionary pressures. As such, these systems play important and varying roles for animals that influence behavior. Sensory systems aid in predator detection and avoidance (Dial and Schwenk 1998), prey location and capture (Garamszegi et al. 2002), mate location (Shine et al. 2005), and even habitat orientation (Costanzo 1989; Reinert and Zappalorti 1988). Animals are evolutionarily shaped by all aspects of their environment and species often utilize certain sensory systems more heavily than others. In extreme cases, some species have lost entire sensory systems (e.g., the loss of eyes in blind cave fish, *Astyanax mexicanus* [Jeffery and Martasian 1998]). In zoos and similar institutions, animal caretakers develop species-specific husbandry, breeding, enrichment, and training programs that are largely based around sensory and behavioral ecology.

Training is commonly employed by zoos for various purposes (Ramirez 1999). A well-designed and scientifically validated training and enrichment program can benefit animal husbandry, improve animal and trainer safety, and enrich the lives and increase the well-being of animals maintained in a captive environment. Training also increases activity levels and provides mental stimulation for animals in managed care (Ramirez 1999).

When developing any training program, it is important to consider the sensory and behavioral adaptations of the focal animal. Crocodilians utilize visual signals such as a wide range of postures and head slaps atop the water's surface, which play an important role in crocodilian communication (McMahan 2001). When training crocodilians in captivity, this visual communication channel has been used successfully by implementing visual cues such as targets and stations (Augustine 2009). One of the most fundamental and applicable behaviors used for training is targeting, an animal touching a part of its body to a defined object or "target" (Ramirez 1999). Once targeting is learned the animal can be conditioned to "station," or remain at a specific object or place for a predetermined length of time. These two behaviors allow trainers to safely and easily direct and work with an animal. Operant conditioning to a target and/or station can be utilized as a safe and effective way to obtain desired behaviors in crocodilians. In addition to natural history, the animal's cognitive abilities should also be taken into consideration when developing a training program. The ability of reptiles to learn has been demonstrated in several species (Augustine 2009, 2011; Burghardt et al. 2002; Bustard 1968; Leal and Powell 2011; Manrod et al. 2008).

At the Wildlife Conservation Society's Bronx Zoo, crocodilians are trained to increase safety and improve husbandry. When a training regimen for crocodilians is instituted, a specific color target or station is chosen for each individual animal. For animals that are or will be housed together, we choose two colors on opposite ends of the grey scale. We are not aware of literature that discusses the ability to distinguish between colors or shades in the Nile Crocodile (*Crocodylus niloticus*), a species with which we have had success with training in both group and individual settings.

The Nile Crocodile is a large predator native to Africa that can grow up to 6 m (Trutnau and Sommerlad 2006). It is likely due to this impressive size that *C. niloticus* is relatively common in zoos (39.16.3 [= males, females, unsexed] individuals being kept in 14 institutions in North America; International Species Information System search 25 April 2012). The staff at the Bronx Zoo has had success with conditioning Nile Crocodiles to target and station both as individuals and in pairs. The lack of evidence suggesting crocodilians can behaviorally distinguish between colors led us to question our methodology of assigning different colored plastic discs to individual animals within the collection. Herein, we examine the response of 0.1 *C. niloticus* previously conditioned to a yellow station when presented with a choice between yellow and black stations.

Materials and Methods.—The Bronx Zoo obtained a six-year-old female Nile Crocodile on 25 April 2008 from Crocodile Creek, Kwazulu-Natal, Republic of South Africa. A consistent operant conditioning program began in May 2008, focusing on targeting

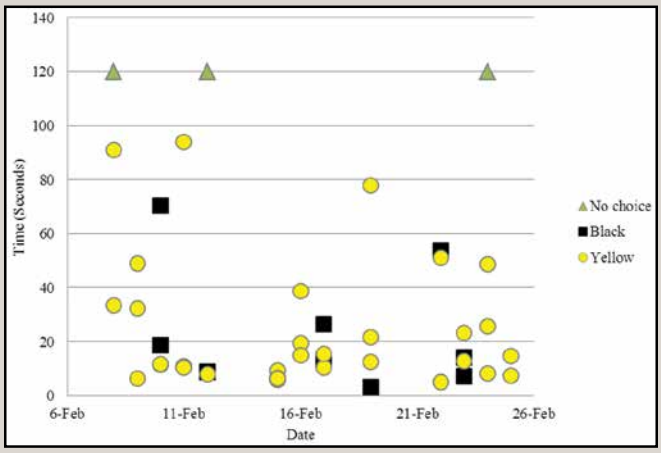

Fig. 1. Time (in seconds) it took for one female *Crocodylus niloticus* to choose a station. Choices were yellow (yellow circles) black (black square) or no choice (green triangle).

and stationing behaviors. The crocodile is housed in a two-part enclosure with a shift door between the two sections. The front portion of the enclosure (exhibit) is approximately 18 m^2 with a pool 2.3 m × 4.7 m and 0.5 m deep. The enclosure has a cement base with two plants, two logs, and a basking spot. The back, off-exhibit section of the enclosure (holding) measures 15.8 m^2 with a pool approximately 2.6 m × 3.5 m and 0.7 m deep. Two sand beaches, each with a tree, encompass one-half of the area and a basking spot is provided on the larger of the two beaches. The land portion of the exhibit connects through a shift door to the larger beach in the holding. This crocodile began shift training between exhibit and holding in 2010. When training for this experiment commenced on 8 February 2011, the female crocodile was conditioned to a yellow target and station (first using a painted pole and then to a yellow plastic disc) and to shift between exhibit and holding on cue.

Ten eyebolts (3 ¾" × 1 ¼" with ¾" opening) were secured along the back wall of the holding and labeled 1 through 10 from left to right. They were positioned one foot apart and at equal heights ca. 3 m above the pool. Two plastic discs, one black and one yellow, were attached to broom handles with a hook-and-eye and metal latch to allow for suspension from the eyebolts positioned along the back wall. This back wall is directly across from the shift door, separating exhibit and holding to ensure that she would see both plastic discs immediately. The crocodile had not been previously exposed to the black disc. Each colored disc was randomly assigned to a specific eyebolt for each trial. Every trial began by targeting the crocodile in her exhibit to a yellow target pole. She was always rewarded with small mice for the completion of this behavior. The shift door was then opened and when the crocodile passed through the shift door she was requested to "station" with a verbal cue. Once all four of her feet were in the water of the holding pool, a timer was started. Final choice was determined when she approached within 1 inch of the station or plastic discs at which point the timer was stopped. If she chose yellow, the color to which she was conditioned, she was rewarded. If she chose black, she was not rewarded and no action was taken. Both discs were removed immediately after the trial and the crocodile was shifted back to the exhibit. This process was repeated at random intervals throughout the day for the duration of this study (17 days). If she failed to choose a disc within a two-minute time frame, she was marked with a zero. We recorded the position of each disc, the color chosen and the time it took for her to complete the behavior. It was also recoded if she chose not to participate by not shifting.

Results.—A total of 48 trials were conducted over 17 days. The animal did not participate during two trials by not shifting into the rear pool; these trials were excluded from analyses. There were 4 trials where she did not choose a color/shade within the two-minute time restriction. The crocodile chose yellow 71.7% of the time and black 19.6% of the time. She was significantly more likely to choose yellow, regardless of position (33 out of 46 times; Chi Square test, $p < 0.001$). However, if she chose black, she only chose it when it was placed on the right side (9 out of 9 times, Chi Square test, $p = 0.003$). There was no relationship between how long it took her to choose and the date in which we performed the trial (Spearman Correlation, $p = 0.268$, $\alpha = 0.05$; Fig. 1).

Discussion.—Crocodilians have fairly good eyesight and their elliptical pupil has great light-gathering ability (McMahan 2001). The crocodilian eye contains single rods (detect presence or lack of light; Kolb 2003) and single and double cones (distinguish between different frequencies of light; Kolb 2003), possibly suggesting an ability to see color (Gans and Parsons 1970; Laurens and Dewiler 1921). Jacobs (1981), however, does not equate the presence of cones to an ability to see color. Certain reptile genera possess rods and four spectral classes of cones, each representing one of the five visual pigment families, which suggests, at least, the potential for tetrachromatic color vision (Bowmaker 1998). Although there is no documentation of crocodiles having color vision or the ability to distinguish different shades along our visible color spectrum, American Alligator (*Alligator mississippiensis*) and caiman (*Paleosuchus* sp.) both have blue- and green-sensitive single cones, and *A. mississippiensis* has a type of cone that absorbs red light (Sillman et al. 1991). The potential for these dangerous predators to utilize color vision could prove to be a useful tool in captive management.

The crocodile examined in this study was previously conditioned to approach the yellow disc but had never been exposed to the black disc. We speculate that if the animal had been preconditioned to the black disc, and never rewarded for approaching it, the percentage of times she went to the black disc during the study (19.6%) would have been significantly lower. We hypothesize that she approached the black station to test or determine the outcome of such an action.

The use of color/shade training can be an important management tool when working with multiple animals in an enclosure, particularly when they pose a threat to one another in times of high excitation such as feeding or breeding introductions. Animals are often separated to decrease or avoid these types of dangerous interactions. Color or shade training has been used with several types of animals in managed collections, including horses (Smith and Goldman 1999), parrots (Pepperberg 1987), primates (Cole 1953), seals (Wartzok and McCormick 1978), and crocodilians (Jepsen, pers. comm.). Although evidence for color vision in crocodiles is scant, we examined whether Nile Crocodiles can distinguish different color stations, at minimum on a gray scale. The results of this experiment demonstrate that the crocodile was able to distinguish between the black and yellow stations, choosing yellow, the previously conditioned station, significantly more often than black (33 out of 46 times), regardless of the position of the station. This would be expected since her entire reinforcement history has been with yellow objects.

This Nile Crocodile was able to discriminate between the two discs when presented with a choice. The crocodile could have

noticed the difference on the grey scale, yellow being much lighter then black, or a difference in brightness or luminance (Jacobs 1981). Further studies are needed to provide a more complete understanding of Nile crocodile vision. While the crocodile in this study was able to distinguish between black and yellow, future studies should address different colors that are similar on the grey scale and in brightness. At minimum, this study has indicated that implementing color/shade training and recognition into operant conditioning can be an important method in managing crocodilians, as our subject preferentially chose to station at her previously conditioned color when given a choice.

Advantages of using learned responses to test color or shade recognition include a greater degree of control for the experimenter, the ability to more closely approximate the behavior, and a smaller possibility that the animal will habituate or lose the behavior during testing (Jacobs 1981). Further studies are needed to provide a more complete understanding of Nile crocodile vision, including close examination of the anatomy of the eye. From an animal management perspective, these types of studies can improve captive husbandry; e.g., while feeding multiple animals in an enclosure simultaneously, or separating animals in times of high excitation. Not only will color or shade recognition be a valuable tool for training crocodilians, but it can also create a more visually stimulating environment.

Acknowledgments.—We thank the following past and present employees of the Bronx Zoo's Department of Herpetology for all of their assistance: Megan Baumer, Alyssa Borek, Brandon Casey, Paul Kmiotek, Melissa Nelson, Jennifer Pramuk, and Bill Holmstrom. We would also like to thank Kent Vliet, Gordon M. Burghardt, and Gerald H. Jacobs for their correspondence on this topic. Lastly, we would like to thank Pat Thomas, Don Boyer, James B. Murphy, and Melissa Nelson for reviewing previous versions of this manuscript.

Folklore Husbandry and a Philosophical Model for the Design of Captive Management Regimes

Keeping reptiles and amphibians is an activity enjoyed by many hobbyists worldwide and is also undertaken by zoos, museums, research organizations, and other professional animal care facilities. The United Kingdom pet trade alone consists of over 500 species of reptiles and amphibians (Tapely et al. 2011), including the importing of 100,000 individual reptiles (Rayment-Dyble 2004). Imports into the European Union include many CITES-listed species and therefore many species of conservation concern (Auliya 2003). Furthermore this trade has seen a continuous increase in both numbers and species diversity of animals as the private keeping of such animals has notably gained popularity over the last 10–20 years (Auliya 2003; Barten 2006; Mader and Mader-Weidner 2006; Tapely et al. 2011; Varga 2004; Wilson 2005). From the perspectives of animal welfare and conservation it is important to develop appropriate husbandry regimes so that these species thrive in captivity, and ideally these would be based on some form of empirical data (Arbuckle 2009; Hosey et al. 2009; Kaumanns et al. 2000; Swaisgood 2007; Wiese and Hutchins, 1994).

There has been a steady stream of both published and unpublished studies that have provided data relevant to the husbandry of captive animals, though these vary greatly in quality and detail (Fidgett 2005; Hosey et al. 2009). The herpetocultural literature is no exception to this general trend, but the level of research interest tends to be somewhat lower than in certain other groups, particularly mammals (Anderson et al. 2008; Arbuckle 2009; Hosey et al. 2009). Some recent changes including the creation of the Herpetoculture section in *Herpetological Review* are a step in the right direction and should help to fuel studies allowing keepers to develop an evidence-based approach to husbandry.

It should be noted however that such an evidence base is only of benefit if it is consulted and integrated into captive management plans. Unfortunately, it is often the case, both in professional and private contexts, that evidence-based husbandry is not used for a variety of reasons including lack of information, a belief (either explicit or implicit) that experience is a better guide than research, and lack of encouragement or ability (real or perceived) to pursue such an approach (Arbuckle 2010; Clauss et al. 2003).

The aim of this paper is to draw attention to the problem of folklore husbandry for exotic animals, specifically reptiles and amphibians, and to encourage professional and amateur keepers alike to strive towards applying evidence-based methods to their husbandry routines.

What is folklore husbandry and why does it matter?—The term "folklore husbandry" was coined by Arbuckle (2010) to refer to "methods or supposed 'best practices' [which] become established without proper evaluation, often justified simply because 'it has always been done that way' or for otherwise unknown or poorly substantiated reasons." In essence, it refers to the widespread practice in many professional institutions and among many private keepers of doing things by tradition and/or uncritically accepting anecdotal husbandry information.

An important point is whether this actually matters. After all, many species have been kept successfully for many years and often bred using methods that fit the definition of folklore husbandry. Indeed, this may be the primary reason why such methods have been so widely adopted. It is likely that some folklore husbandry methods will prove to be suitable once they have been properly evaluated. Nevertheless there is an inherent issue in that they have not been adequately tested and so should not be blindly accepted as the best nor the only possible solution. Unfortunately that is how folklore husbandry methods are often portrayed, particularly among private keepers (de Vosjoli 2007).

What can result are dogmatic assertions of the "correct" way of doing things that hamper the further development of methods via condemnation of different practices (de Vosjoli 2007). This is an attitude that is to be discouraged on at least two grounds. Firstly, it is problematic to take any current situation and proclaim it to be the best one possible. This is particularly true for the care of reptiles and amphibians, which is still in a stage of frequent development, as it can directly lead to a decrease in motivation to continue to improve husbandry. In fact the basic natural history and ecology of many commonly kept species are poorly known, reducing further our certainty that a given approach is the best one. Secondly, the successful maintenance of a given species is a matter of degree. One method may give good results but another may confer even better results or improved welfare standards. The idea of encouraging a diversity of husbandry practices is not new, and is in fact a key aspect of de Vosjoli's (2007) "multifactorial model of herpetoculture," although he does not explicitly highlight the benefits of such a philosophy to continual methodological improvement.

In addition to the ideological disadvantages noted above, folklore husbandry can also incur time and financial costs that are of more practical concern. As an example of the former is the removal of beaks from avian prey or the chopping of foods for herbivorous species. These are time-consuming methods that are used with some regularity but their benefits have always simply been assumed by those who perpetuate their use. As an aside, recent research by Plowman et al. (2008) has shown that chopping foods provides none of the perceived benefits and is actually contraindicated in some situations. This is a good example of a folklore husbandry claim perceived as beneficial for numerous reasons, but that on investigation turned out to be false. Application of the results of Plowman et al. (2008) should alleviate the time cost of food preparation for keepers, and in a professional setting where "time is money" should also present a financial saving.

Furthermore it is clear that some folklore husbandry claims, if refuted, would also provide a direct financial cost saving. Arbuckle (2009) found that providing a gut-loading diet with the aim of adequately supplementing calcium was not a successful

KEVIN ARBUCKLE
Institute of Integrative Biology, Biosciences Building, University of Liverpool, Crown Street, Liverpool, U.K., L69 7ZB
e-mail: k.arbuckle@msn.com

approach. However, although supported by a review of previous studies his experimental results did not permit statistical evaluation of this, and therefore require further work to provide concrete evidence. If it does prove to be accurate however, dusting with a relatively cheap supplement may give better results than the use of a specific gut-loading diet, many of which are relatively expensive.

Hopefully, I have now shown that it is important to be aware of folklore husbandry, and to adopt a more evidence-based approach to the care of exotic animals such as reptiles and amphibians. I will now provide some more examples of folklore husbandry that require investigation and also highlight a few studies that have evaluated such claims. I will then offer some guidelines in the form of a framework for establishing a husbandry regime. Finally, I will attempt to encourage dissemination of the basic ideas contained here with the aim of improving husbandry practices in both professional and private collections.

Some examples of folklore husbandry.—Examples of folklore husbandry are ubiquitous and in many cases are so deeply ingrained that they may not be instantly recognized as such. Nevertheless it might be useful to highlight a few of these so that a better idea of what the subject encompasses can be gained. These are somewhat dominated by nutritional examples, and this reflects both my own background and also that captive feeding appears to be a particularly prominent area of research into animal husbandry. Many examples have not been directly examined and the current availability of data to test them is variable. They represent potential for future directed studies and include a wide range of claims.

Do nutritional products such as supplements and "complete" diets that are marketed in a species-specific fashion give better results than equivalent products marketed in a more general way? Given that the nutritional requirements for reptiles and amphibians are for the most part extrapolated from domestic animals (Allen and Oftedal 1994; Baer 1994), the existence of species-specific marketing raises suspicion as to whether any genuine benefit to these products exists. Studies directed at evaluating whether the performance of a given species is better with products marketed for them than others would provide key information to guide which option to use.

Do particular livefood species represent a better staple diet than others? It is a long held belief that locusts are a better staple prey than crickets, and feeder cockroaches have recently become somewhat of a vogue food item that is touted for a high nutritional value. However, despite much published data on nutrient compositions of various invertebrate prey (Finke 2002; Nijboer et al. 2009; Oonincx and Dierenfeld 2011) the relative benefits in practice have rarely been tested. It is an important step to know the composition of a given prey item, particularly compared to another prey item, but in itself this provides no measure of how an animal will perform on that diet. It has previously been highlighted that direct comparison of prey composition to recommended nutrient intake is notable by its absence from most studies (Arbuckle 2009). Furthermore, there are little or no data on nutrient digestibilities for most reptile and amphibian species currently kept, despite the importance of this information for relative assessment of prey species. It is clear that much information is lacking to answer this question with confidence, but many folklore husbandry claims are made apparently without reference to those data that do exist.

Does the substrate influence general activity level or natural behaviors such as burrowing? Despite the almost ubiquitous use of substrates in enclosures, there has been surprisingly little research investigating whether a particular choice is better than any other. There is a plethora of anecdotal evidence available on the issue. For instance I have used a mix of sand, soil, and a few bark chips in an attempt to create a substrate mimicking the reported natural soils of the Plains Hog-nosed Snake (*Heterodon nasicus*). Following the change from newspaper to this substrate I noticed an apparent increase in activity and some burrowing behavior. However, like most such reports this represents a purely untested anecdote. Similarly, based on ecological observations and successful results of the entire husbandry regime used, Bennett and Thakoordyal (2003) strongly recommend the use of deep substrates for burrowing in Savannah Monitor (*Varanus exanthematicus*) enclosures. They particularly advocate soil but mention that others can be used, though the former "is easily the best." While I would personally agree with this last comment, it would be useful to have data from a comparison of various options, providing a direct evidence base to complement the natural history observations.

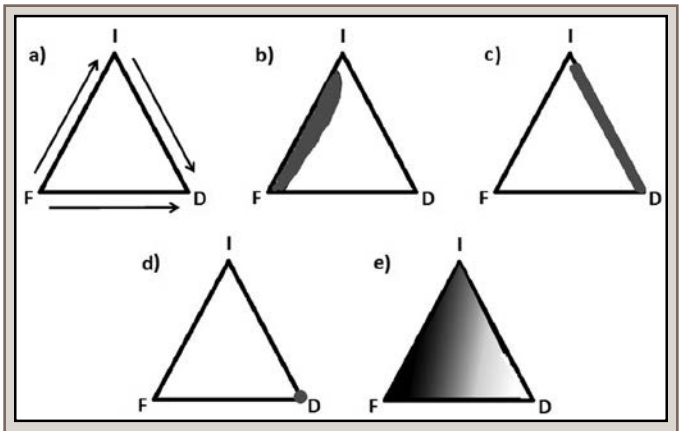

FIG. 1. The FID model of husbandry design. a) Basic model showing arrows representing the directions we should be aiming to move in. b) Shaded area indicates the range of most current designs. c) Shaded area indicates a range of good designs. d) Filled circle represents the ideal design. e) Darker shading indicates higher density of anecdotal evidence. See text for further details. F = folklore husbandry, I = integrated husbandry, D = direct evidence-based husbandry.

Is environmental enrichment necessary for reptiles and amphibians, and if so which form should it take? Enrichment is strongly advocated as a strategy to improve the welfare of captive animals (Swaisgood 2007), but specific considerations for reptiles and amphibians are lacking from most treatments of the subject. The general aim of many enrichment strategies is to increase activity or to encourage natural behaviors (Hosey et al. 2009). The latter aim is probably responsible for the idea that creating naturalistic enclosures promotes good welfare through environmental enrichment (Fàbregas et al. 2011). However, often such benefits are assumed rather than empirically tested. Some notable exceptions exist including Hurme et al.'s (2003) demonstration that an enrichment feeding device for dendrobatid frogs resulted in increased activity, but unfortunately such studies are not the rule. On the basis of natural history observations, Rosier and Langkilde (2011) examined whether the provision of a climbing structure is beneficial to a lizard that regularly climbs off the ground (*Sceloporus undulatus*). In contrast to what might be expected, these authors found no effect on a variety of welfare and behavioral measures. Their study highlighted the non-intuitive nature of providing enrichment, particularly to animals that

are phylogenetically distant from humans. It is a good example of why folklore husbandry claims should be properly tested, not simply accepted because they "make sense."

Can we take information on natural food groups and convert these straight to a captive diet? In other words, if we know that an herbivorous reptile naturally eats 50% leaves, 30% fruit, and 20% other vegetable matter, can we replicate these proportions in captivity? In this example, it is particularly important to note that, although providing some fruit would probably be acceptable, it would be unwise to uncritically make up 30% of the diet with it. One concern is that fruits more than many other plant parts are highly seasonal (Jordano 2000), and so either the absolute amount or the specific fruits eaten or both are likely to vary considerably over the year. This is very different from a constantly high proportion of fruit in the diet. Furthermore, the nutritional content of the food is more important that the "package" in which the nutrients are given to the animal. Schwitzer et al. (2008) highlighted the fact that domesticated fruits, those cultivated for human consumption and taste buds, have a very different nutrient composition to those found in the wild. It seems that wild fruits are actually more similar to cultivated vegetables. Since it is unlikely that most keepers will be able to source the wild fruits that form the natural diet of their animals, it appears as though substituting at least some of the fruit with vegetables in captivity would be preferred. It is likely that further scrutiny of simple "cut and paste" methods will reveal other cases where amendment is needed. This is a case of a partially evidence-based approach but with some aspects remaining under the umbrella of folklore husbandry.

How should we develop husbandry regimes?—With such a spectre hanging over our heads, how should we design our husbandry regimes so as to ensure the best approach we can? Because we must look after our animals now, we don't have the luxury of waiting for a full evaluation of every technique we use and thus we must act with imperfect knowledge. It is certainly true that the reason so many folklore husbandry claims exist is because we simply do not currently have the information to test them—in many cases we have to reserve ourselves to using such methods if we are reasonably confident they will be effective.

The goal should be to implement each part of a given animal's care with the best information available. This can be conveniently divided into three levels of increasing reliability: folklore, integrated, and direct evidence-based husbandry. The former has already been described and so needs no more definition here. Before discussing the other two approaches I should emphasize that although they are discrete categories, any given regime will undoubtedly incorporate all three. Despite the negative light under which I have cast folklore husbandry, as previously mentioned it is prevalent due to the fact that it works (at least to some degree) in many cases. It thus has a place in husbandry regimes when no better information exists as it can represent a conservative approach providing its limitations are borne in mind.

Integrated husbandry is the most common form of evidence-based husbandry and was the view detailed in Kaumanns et al. (2000). It involves integrating the existing ecological and, more generally, biological information on a given species, and assimilating this into a husbandry plan that attempts to mimic nature. This has important benefits in that such information is available for many species, albeit the quantity and quality will vary widely. However, it suffers from two main constraints.

Firstly, as highlighted above care must be taken to ensure that it is the important parts of the information that are replicated. There is no sense in providing a diet with the same set of food groupings as the natural diet if the nutrient composition is vastly different. Similarly, providing light for many species is not as important as providing the appropriate quality of light to enable biosynthesis of vitamin D in the skin.

Secondly, there may be differences between captive animals and their wild counterparts that impact the husbandry methods used or the evaluation of such methods. The captive environment differs from the natural habitat, and different species will not necessarily respond to this in the same way (Mason 2010). Although such differential responses to captive stressors are perhaps unsurprising, other effects of short- and long-term periods in captivity have been noted that are less intuitive. Captive animals have been shown to diverge from their wild counterparts in behavior (Guyon 2009; McPhee 2003), physiology (Studier and Wilson 1979), and even morphology (Moore and Battley 2006; Moss 1972; O'Regan 2001), all of which might have implications for the application of field-collected data to captive management.

Integrated husbandry is an excellent way of introducing an evidence-based approach to captive management, especially since data are far more abundant than for direct evidence-based husbandry. It can also act as an information platform from which hypotheses for direct empirical studies can be based. However, it does have some limitations which should be recognized and we should not accept it as the be-all-and-end-all of husbandry methods.

Direct evidence-based husbandry on the other hand represents the gold standard. It involves empirical examination of methods used and ideally their alternatives. An ongoing example of this is work on the use of ultraviolet B (UVB) lamps to create an appropriate lighting regime in captivity. It is beyond the scope of this paper to offer a thorough discussion of the issue, but comparisons of the light output of different bulbs currently in use (Schmidt et al. 2010) combined with a field study on exposure that is used to provide guidelines in captivity (Ferguson et al. 2010) is a commendable endeavor.

Although forming a discrete category of information, direct evidence-based husbandry often follows folklore and integrated husbandry by using them to generate hypotheses. For instance, a direct study might aim to evaluate a folklore husbandry claim or might be designed to test whether a particular integrated strategy does indeed offer the benefits it proposes in captivity. Once empirically examined, such methods can then be discouraged or elevated to the direct evidence-based category.

The main limitation of this approach is the time and financial resources necessary to investigate each technique, and as a result data from direct studies are lacking for most methods currently in use. With time and effort however, we can increase the proportion of any given husbandry regime that results from a direct evidence-based approach.

The FID model.—I have divided husbandry methods into three discrete categories, but emphasized that these categories will often combine in various proportions to result in the complete husbandry regime. This perspective can be represented by a simple visual model, consisting of a ternary diagram with folklore (F), integrated (I), and direct evidence-based (D) husbandry at separate corners (Fig. 1). In this case each corner represents 100% use of that principle.

The strategy illustrated by the FID model is an attempt to push our husbandry regimes as far as possible in the direction of the arrows (Fig. 1a). In no case should we try to move towards F but the ultimate goal is to use a regime that is as close to D

as possible. If we are close to F then we should look at moving towards either I or D (the side ID represents an evidence-based approach). If we are close to I then the preferred direction would be towards D.

In many cases it is useful to talk about a range of possibilities for the reasons highlighted earlier. Most current designs lie near the side FI (Fig. 1b). This is largely due to the fact that often there are few direct data to rely on, but where this applies we can still attempt to move towards I. Similarly we can denote a range of good approaches which lie along or close to side ID, those which are heavily evidence-based (Fig. 1c).

The ideal scenario would be to have perfect knowledge of the best option (or range of options) to use, and this would lie on corner D (Fig. 1d). Unfortunately this ideal situation is unlikely to be fully realized, certainly for most species and in the near future. However, just because this hypothetical scenario represents 100% direct evidence-based husbandry does not imply that an integrated approach should not apply. As discussed above many direct evidence-based methods are and will be a result of formal tests of integrated methods in captivity. It is not the case that the former will overturn all integrative (or even folklore) husbandry methods, but might often confirm them such that they receive more support and are thus elevated to the status of direct evidence-based.

Finally, it is also worth discussing where anecdotal evidence enters this framework since it has not been explicitly covered here. The reason for this is that anecdotal evidence cannot be allocated to any discrete category and often arises in part from two or even all three categories described here. Nevertheless it is possible to make some comments on its distribution since anecdotes are not expected to occur evenly through the parameter space in the FID model. Anecdotal evidence is expected to be most prevalent near F, showing a decreasing presence through I and declining to zero at the ideal point on D (Fig. 1e).

Note that anecdotes are still expected to be moderately common even in regimes that use a high degree of integrated husbandry; this is a result of the limitations of such an approach highlighted above. Note also that I do not regard them as equivalent to folklore husbandry, despite a strong relationship between them. This is because although they share many similarities, a single piece of anecdotal evidence can be influenced by both folklore and evidence-based methods. In contrast, by definition a folklore husbandry technique is not a result of any evidence-based approach, either direct or integrated.

Finally, and in common with folklore husbandry, although we should aim to move away from anecdotal evidence it is not necessarily a bad thing in all cases. For instance, where better approaches are lacking an anecdotal observation can steer the keeper away from poor practices. Furthermore, anecdotal observations can also provide new hypotheses for further examination and in that sense can contribute to development and improvement of husbandry regimes.

A call to action.—I hope that the ideas presented above can be used to improve professional and private captive management regimes. However, this is only likely to happen if they can stimulate new research and implementation of that research. In this vein, I rely on two (non-mutually exclusive) groups of people for this: researchers and keepers.

Researchers with an interest in animal husbandry and welfare should focus on evaluating folklore husbandry claims and providing a direct evidence base for use by keepers. Aside from such direct studies, reviews of the biology and particularly the ecology of a given species would also be useful, if written from a practical perspective aimed at informing husbandry. Such reviews can provide a good background for integrated husbandry regimes and can give recommendations for further studies. Given the practical nature of such research, I believe that the workers involved have a responsibility to make their studies available to those who can apply their findings, wherever possible. The best study on animal husbandry is useless if keepers cannot read it.

Keepers have a responsibility to share their knowledge and ideas. This should not be a problem since it is the sharing of information that leads to folklore husbandry in the first place. However the important point is that keepers should foster an attitude of awareness of different perspectives on husbandry, particularly folklore husbandry. With an understanding of the different categories of methods and their limitations keepers can evaluate the reliability of any information received.

When disseminating information keepers should make an effort to explain why a particular method is done, not simply pass it on in a manner that promotes parroting of poorly substantiated claims. Finally, it is also the responsibility of keepers to retain an open (but critical) mind to new methods. Trying new methods is the only way we can ultimately improve our husbandry practices, particularly if these represent at least a partially evidence-based approach. This is what we as keepers should continually strive to do, for the benefit of all concerned.

HERPETOCULTURE NOTES

SQUAMATA — LIZARDS

***AMEIVULA ABAETENSIS*. DRINKING BEHAVIOR.** Many reptiles have morphological adaptations (Sherbrooke et al. 2007. Zoomorphology 126:89–102) and behavioral strategies (Al-Sadoonet al. 1999. Saudi J. Biol. Sci. 6:91–101) for the acquisition of water in the environment, with documented cases of convergent adaptations for species in arid environments (Comanns el al. 2011. Beilstein J. Nanotechnol. 2:204–214). *Ameivula abaetensis* is a diurnal lizard species, endemic to the sand dune habitats ("restinga") along the Brazilian coastline. The geographic distribution of the species extends from the north coastline of Bahia State in Salvador Municipality, to Santo Amaro de Brotas Municipality in Sergipe State (Dias et al. 2002. Copeia 2002:1070–1077). Previous research by Santa-Rosa et al. (2012. Bol. Mus. Biol. Mello Leitão 29:53-63) suggested that the ingestion of *Byrsonima microphyla* fruits by *A. abaetensis* may be an important source of water in restinga habitat during the dry season. This note reports drinking behavior in *A. abaetensis*.

Two independent groups of *A. abaetensis* were kept in captivity during the period of 28 February to 25 April 2009 (N = 8), and 20 to 27 October 2012 (N = 6). The specimens were collected during field activities, in the sand dunes habitat in Restinga do Abaeté, Salvador, Bahia (12.9283°S, 38.3358°W; datum WGS84), and they were kept in captivity for behavioral observations (license nº 31047-1/SISBIO). The climatic and structural conditions of captivity (terrarium with dimensions 100 × 100 × 100 cm) were very similar to those found in the natural microhabitat inhabited by the species (Dias and Rocha 2004. J. Herpetol. 38:586–588; Dias et al. 2005. J. Herpetol. 15:133–137; Dias and Rocha 2007. Braz. J. Biol. 67:41–46), but the specimens were kept sheltered from direct sunlight. For the first group, we provided fruit (*B. microphyla*) and water for sustenance in shallow containers. For the second group, we provided small beetles and water. For

both conditions, during *ad libitum* observations, we recorded the drinking behavior at 1300 h on 20 April 2009 and 1000 h on 25 October 2012 using an SLR camera. In both treatments (with and without the availability of fruit), it was possible to verify the drinking behavior. The behavior consisted of approaching the water source, followed by the animal lowering its head and using its tongue to collect water. Once the water was obtained, the animal raised its head, keeping it perpendicular to the soil surface for up to five seconds. Further, the animals simultaneously kept their front limbs flexed, such that the anterior ventral surface of the body was not in contact with the ground.

Although there are no published data concerning ingestion of water in natural habitat for *A. abaetensis*, these observations suggest that this behavior can be common when water is available in a xeric ecosystem, despite water availability within the diet (e.g., *B. microphyla*). The opportunistic behavior of drinking water has been described in other species of heliophilous lizards (Ribeiro and Freire 2009. Herpetol. Rev. 40:228–229) and it can be considered a convergent behavioral adaptation for lizards occurring in habitat with low water availability.

***PHRYNOSOMA ASIO* (Giant Horned Lizard). DRINKING BEHAVIOR.** Stereotypical behaviors surrounding water intake in the genus *Phrynosoma* have been well reported (Mayhew and Wright 1971; Peterson 1998; Sherbrooke 1990). Desert lizards like *Phrynosoma* rarely have access to bodies of water and are adapted to take little or no water for long periods of time (Meyer 1966). Herein we report an unknown and unusual water ingestion method in *P. asio*, a horned lizard widely distributed in southwest Mexico (Reeve 1952). On 30 April 2012 we observed a captive female *P. asio* (95 mm SVL) dipping her head, neck, and forelimbs into the water trough of her terrarium while making light and leisurely sucking motions with her throat (Fig. 1). We also recorded the behavioral display time, having a duration of 7 minutes and a repeat of the same behavior the next day with a duration of 5 minutes. The knowledge of this horned lizard's ecological and ethological aspects are relatively little documented (Pianka and Parker 1975). We thank Oscar Avila Morales, Jonathan Vazquez Sanchez, and Jose Antonio Rosas by supporting us in the field and Tania Raya Garcia for support in caring for the specimen in captivity.

FIG. 1 Adult Female *Phrynosoma asio* exhibiting their water intake behavior.

SQUAMATA — SNAKES

***CROTALUS OREGANUS OREGANUS* (Northern Pacific Rattlesnake). LONGEVITY.** At a local non-profit education center in Mather, California, USA, we believe we have one of the oldest captive rattlesnakes on record. During the spring of 1982, a small juvenile male *Crotalus oreganus oreganus* was collected in Auburn, California, USA, by a student attending Placer High School. It was presented to Placer High biology teacher, Douglas Stryker, who kept the specimen as an educational classroom pet. The snake was kept in the classroom for 31 years. Recently Mr. Stryker retired, and in November 2012 the snake was given to a local non-profit, Sacramento Splash, and now resides in the Splash Education Center.

Crotalus oreganus are typically born in the fall, but do not emerge until the following spring (Diller and Wallace 1984). As this specimen of *C. o. oreganus* was collected as a small juvenile in the spring, it is believed to have been born in the fall of 1981. This makes this *C. o. oreganus* over 31 years old at the time of submission (April 2013). We believe this is the oldest *C. oreganus* on record and among the oldest *Crotalus* that have been recorded.

The average lifespan for *C. oreganus* in the wild is approximately 20 years (Fitch 1949). A captive *C. o. oreganus* that was recorded at 22 years, 7 months is reported by Slavens (http://www.pondturtle.com/lsnaked.html#Crotalus). Still, no records document an individual *C. o. oreganus* older, or even close to the age of the snake reported herein.

IAN EVANS and **LU-ANNE SPENCER-HARTLE**, Sacramento Splash, Mather, California 95655, USA (e-mail: Luanne@sacsplash.org).

***MASTICOPHIS MENTOVARIUS* (Neotropical Whipsnake). REPRODUCTION.** *Masticophis mentovarius* is a neotropical colubrid that ranges from northern Mexico to northern South America (Lemos-Espinal and Smith 2007. Amphibians and Reptiles of the State of Chihuahua, Mexico. CONABIO-UNAM. 178 pp.). The reproductive mode is oviparous and, at least in a population in Veracruz, Mexico, wild females are gravid from April to May (Pérez-Higareda et al. 2007. Serpientes de la Región de los Tuxtlas, Veracruz, México. UNAM. 189 pp.). Eggs have been reported to be laid inside abandoned burrows or cracks in the ground (Vázquez and Quintero 2005. Anfibios y Reptiles de Aguascalientes. CIEMA-CONABIO. 197 pp.). In populations studied, the eggs are white and are laid in clutches of 17–20, have a granular surface, are not adhesive to one other, and measure 46–64 mm

in length, 26–36 mm in diameter (Lemos-Espinal and Smith, *op. cit.*).

The herpetology laboratory at Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México, supports a diverse live collection of reptiles and amphibians. The majority of them are Mexican species. The collection includes *Masticophis* spp., including two individuals of *M. mentovarius*. Here we report reproductive information about this species, based on our observations in recent years, including timing of copulation events, clutch production, hatchings, and egg sizes.

Between 1991 and 2000, four copulation events were recorded, two during February and two during March. Four clutches have been laid, two in April and two in July (9, 7 and 2, 5 eggs respectively). Two clutches have hatched during June (4 and 5 hatchlings respectively); on this last clutch, the eggs (N = 5) had a mean mass of 5.14 g, mean length of 42.8 mm, and mean width of 16.4 mm.

During 2008 and 2009 we recorded two additional reproductive events. In April 2008, in an exhibition enclosure (165 × 165 × 65 cm), copulation was observed; temperature was 28–30°C and relative humidity (RH) was 50–70%. The male (1330 mm SVL) came from the state of Morelos and the female (1180 mm SVL) was from the state of Guerrero, Mexico. On 7 July 2008, the female laid a clutch of 11 eggs, of which six were judged to be in good condition. Those eggs were incubated at 28–30°C and a RH of 50–70%. The mean weight of the eggs was 11.30 g. Two hatchlings were found on 13 and 14 August (mean mass 7.73 g, mean SVL 221.1 mm). On 19 August the rest of the eggs were discovered in poor condition and four snakes were found dead inside the eggs (mean mass 5.74 g, mean SVL 194.5 mm).

The second observation was on 13 February 2009. The same pair of *M. mentovarius* produced a clutch of nine eggs (mean mass 13.83 g, mean length 49.9 mm, and mean width 21.4 mm). The eggs were infertile.

BEATRIZ RUBIO-MORALES (e-mail: betyrm@unam.mx), **SANDRA FABIOLA ARIAS-BALDERAS, ALFONSO HERNÁNDEZ-RÍOS, FELIPE CORREA-SÁNCHEZ,** and **EDUARDO CID-MÉNDEZ**, Laboratorio de Herpetología, Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México, 54090, México.

***THAMNOPHIS RADIX* (Plains Gartersnake). REPRODUCTION / LITTER SIZE.** Brood (litter) sizes for *Thamnophis radix* are well documented, and are known to vary by geography, size (and age), and prey availability (Engeman et al. 2002. Herpetol. Rev. 33:59; Fitch 1985. Misc. Publ. Univ. Kansas Mus. Nat. Hist. 76:1–76; Stanford and King 2004. Copeia 2004:465–478). Blackburn and Stewart (2011. *In* Aldridge and Sever [eds.], Reproductive Biology and Phylogeny of Snakes, pp. 119–181. Science Publishers, Enfield, New Hampshire) report the largest known litter size for *T. radix* to be 92.

FIG. 1. All 90 of the seemingly healthy offspring produced by a large *Thamnophis radix* collected in Edmunds Co., South Dakota.

During the fall of 2011, MZ collected a large adult female *T. radix* along a busy highway in Edmunds Co., South Dakota, USA. The female was kept in an enclosure with an adult male *T. radix* and both were hibernated during the winter. The pair was kept in the enclosure until early August 2012 at which time the male was moved into a separate enclosure in anticipation of the female giving birth. Starting on the evening of 9 August 2012, the female gave birth to one unfertilized ovum, six stillborn, one malformed, and 90 seemingly healthy offspring (Fig. 1). Three of the stillborn and the single live malformed offspring displayed bicephaly. The production of 97 offspring represents the largest brood for *T. radix* documented to date.

We thank Erica P. Hoaglund and John J. Moriarty for reviewing this note.

First Report of Ranavirus in Plethodontid Salamanders from the Mount Rogers National Recreation Area, Virginia, USA

Ranaviruses are an emerging pathogen responsible for numerous amphibian die-offs throughout Europe and North America (Miller et al. 2011). In the southeastern United States, local anuran die-offs due to ranavirus have been observed (Green et al. 2002; Hoverman et al. 2012; Todd-Thompson 2010), and suggested to contribute to local species declines (Gray et al. 2009a). The southern Appalachian Mountains have one of the greatest global diversities of plethodontid salamanders (Dodd 2004), and disease emergence could have devastating impacts on community structure and ecosystem function (Whiles et al. 2006). Ranavirus infections have been reported in 14 species of plethodontid salamanders occurring in the southern Appalachian Mountains (Miller et al. 2011). Initial surveys for ranavirus infections have focused on the Great Smoky Mountains National Park (81% prevalence; Gray et al. 2009b), which is known for high species richness of plethodontid salamanders (Dodd 2004). However, much of the remainder of the southern Appalachian Mountains has not been investigated except for a single study in the Ridge and Valley physiographic province of Wise County, Virginia (33% prevalence; Davidson and Chambers 2011). Many other Appalachian peaks have high plethodontid salamander richness and include many species with limited distributions, but the occurrence of ranavirus in these communities is unknown.

We sampled salamanders in the Mount Rogers National Recreation Area (MRNA), Virginia from Whitetop and Beech Mountains (Grayson, Smyth, and Washington counties). Many species reach the extreme northern limit of their range on these mountains with 15 species of plethodontid salamanders found on Whitetop Mountain alone (Organ 1991). Our sampling focused on five species with aquatic larval stages (i.e., complex life cycle), which have shown higher prevalence of ranavirus infection (Gray et al. 2009b), and four terrestrial-breeding species with direct development. Nine species that we targeted for sampling included: Northern Dusky (*Desmognathus fuscus*), Seal (*D. monticola*), Blue Ridge Dusky (*D. orestes*), Northern Pygmy (*D. organi*), Black-bellied (*D. quadramaculatus*), Blue Ridge Two-lined (*Eurycea wilderae*), Northern Gray-cheeked (*Plethodon montanus*), Ravine (*P. richmondi*), and Weller's (*P. welleri*) salamanders. In Virginia, Weller's, Northern Pygmy, Blue Ridge Dusky, and Blue Ridge Two-lined salamanders are listed as species of greatest conservation need (Virginia Department of Game and Inland Fisheries 2005).

Salamanders were captured along transects from June to August 2008 and May to August 2009 from Byars Creek (1158–1311 m elev.; 36.62755°N, 81.58903°W), Whitetop Creek (1158–1615 m elev.; 36.64016°N, 81.60040°W), Dells Branch (945–1585 m elev.; 36.64774°N, 81.60254°W), Beech Mountain (956–1097 m elev.; 36.63362°N, 81.63030°W), and Daves Ridge (1128–1433 m elev.; 36.6475°N, 81.59185°W). Each transect was positioned perpendicular to the elevational gradient centered on either a stream or ridge line. We searched for salamanders on each side of the transect for one person-hour (~150 m) at every 30.5 m of elevation by turning all cover objects. We placed each captured salamander in individual 1.2-liter plastic bags. We used sterile forceps to remove a small tail section along the natural break point and placed each sample in a sterile microcentrifuge tube with 99% reagent grade isopropyl alcohol. We used a different set of sterilized forceps for each individual tail sample. Between sampling events, forceps were autoclaved to destroy remnant DNA.

We extracted genomic DNA from tail samples using a DNeasy Blood and Tissue Kit (Qiagen Inc., Valencia, California), and used a Qubit™ fluorometer to quantify the concentration of genomic nuclear DNA from tail samples. Samples from 2008 (N = 99) were extracted and quantified at the Diagnostic and Investigational Laboratory in the College of Veterinary Medicine at the University of Georgia (UGA). In 2009, we extracted and quantified the 2009 samples (N = 320) in the Center for Wildlife Health at the University Tennessee (UT). Real-time qPCR was performed using the identical primers and protocol of Gray et al. (2012). The qPCR was conducted using a SmartCycler system (Cepheid, Sunnyvale, California) for 2008 samples and an ABI 7900HT PCR system (Live Technologies Corp., Carlsbad, California) was used for 2009 samples. Controls included two positive controls (cultured virus and known positive tadpoles) and two negative controls (water and known negative animal). The qPCR was run in

TABLE 1. Ranavirus prevalence in salamander communities inhabiting Whitetop Mountain (Grayson, Smyth, Washington counties), Virginia, USA.

Species	No. infected / total no. sampled	Prevalence of infection (95% confidence interval)
Desmognathus fuscus	1 / 11	0.09 (0.02–0.37)
Desmognathus monticola	2 / 22	0.09 (0.03–0.28)
Desmognathus orestes	3 / 145	0.02 (0.01–0.05)
Desmognathus organi	3 / 70	0.04 (0.01–0.12)
Desmognathus quadramaculatus	1 / 32	0.03 (0.01–0.16)
Eurycea wilderae	0 / 5	0 (0–0.44)
Plethodon montanus	3 / 101	0.03 (0.01–0.08)
Plethodon richmondi	0 / 3	0 (0–0.56)
Plethodon welleri	1 / 30	0.03 (0.01–0.17)
Total	14 / 419	0.03 (0.02–0.06)

duplicate and a C_T value ≤ 30 was deemed positive, according to equipment optimization at UGA and UT.

Our results document the first known presence of ranavirus infection in amphibians of the MRNA. Salamanders sampled and all other salamanders observed did not display external signs of ranavirus infection such as swelling or ulcerations (Miller et al. 2011). We detected ranavirus in seven salamander species (Table 1)—four of the species were first-time detections: Weller's, Northern Pygmy, Blue Ridge Dusky, and Northern Gray-cheeked (Miller et al. 2011). Ranavirus prevalence ranged from 3–9% within species, and was 3% among all species that tested positive (Table 1). Infected salamanders were found between elevations of 945–1554 m, and along all transects except Daves Ridge. Species with a more aquatic life history (*D. fuscus* and *D. monticola*) had the highest prevalence of infection (9%), as reported by Gray et al. (2009b). However, there was no association between larval life history (aquatic larvae or terrestrial direct development) and infection status ($\chi^2 = 0.01$, $p = 0.920$), which may be a consequence of low overall prevalence. Additionally, there was no association between sampling years ($\chi^2 = 0.196$, $p = 0.658$).

Our low detection of ranavirus infection could be partly influenced by the type of tissue collected. Gray et al. (2012) demonstrated that tail clips produced false-negative results for 20% of tail samples in American Bullfrog (*Lithobates catebeianus*) tadpoles when compared to liver tissue samples and suggested that false negatives could relate to the sensitivity of the amphibian host. Even with the possibility of a 20% false detection rate, salamanders from the MRNA appear to have lower ranavirus prevalence than salamanders from the Great Smoky Mountains National Park (81%; Gray et al. 2009b) and Wise County, Virginia (33%; Davidson and Chambers 2011). Future research could include histological analyses to reduce the potential of false negatives (Gray et al. 2012) as well as genetic sequencing to identify the strain(s) of ranavirus present in the MRNA.

We documented ranavirus infections occurring in secluded areas (often ≥ 300 m from trails, roads, or other areas of public activities) of the MRNA, indicating that this pathogen is not always associated with human-impacted sites (Gray et al. 2007). We documented infections in four additional species of plethodontid salamanders, including rare species. Weller's Salamanders are an IUCN (2008) Red List species, and our positive results from this species are a concern suggesting that further monitoring may be warranted. These results provide additional evidence that ranavirus could be distributed throughout the Southern Appalachian Mountains. In the MRNA, ranavirus was found to infect both rare and more abundant salamanders as well as those with aquatic or terrestrial embryonic development, suggesting that ranavirus is not selective and any southern Appalachian salamander could be at risk. Additionally, six other species of plethodontid salamanders, Eastern Newts (*Notophthalmus viridescens*), and five anuran species are found in the MRNA, but were not part of this study (Hamed, unpubl. data). Given the tendency for anurans to be more susceptible to ranavirus than salamanders (Hoverman et al. 2011), frogs may be important reservoirs and amplifying hosts for ranavirus (Paull et al. 2012). It would be prudent to include all amphibian species in future monitoring designs to provide a more comprehensive understanding of ranavirus prevalence in the MRNA, and to increase the likelihood of identifying amplifying species and disease hotspots (Paull et al. 2012).

Acknowledgments.—This research was completed with funds provided by the Virginia Department of Game and Inland Fisheries through a State Wildlife Grant from the U.S. Fish and Wildlife Service and additional funding from the University of Tennessee Institute of Agriculture. We extend special thanks to James and Della Organ for providing sampling locations and guidance. We thank Gary Poe and Brian Parks for assistance in collecting and Becky Hardman, Kate Carpenter, and Lisa Whittington for assistance with molecular testing and extraction. Additionally, we are grateful to the MRNA staff for project assistance and to many private land owners for access to our study sites. This manuscript was improved with comments from Trang Nguyen, Dede Olson, and two anonymous reviewers. All sampling was approved by the Virginia Department of Game and Inland Fisheries (Scientific Collection Permit #41396) and followed UT Institutional Animal Care and Use Committee protocol #2084-0412.

Batrachochytrium dendrobatidis in South Dakota, USA Amphibians

Although the amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), has been well-studied across the United States, there are still several regions where little is known regarding its presence or prevalence (Oullet et al. 2005; www.Bd-maps.net). Currently, there is no information regarding *Bd* occurrence in South Dakota, yet of the 15 amphibians species known to reside in South Dakota, many have been documented as hosts to *Bd* in other states (Oullet et al. 2005; Woodhams et al. 2008). Additionally, neighboring states have documented the presence of *Bd* in these and other species (Hossack et al. 2010; Rodriguez et al. 2009). To help fill the knowledge gap for South Dakota, we sampled for the occurrence of *Bd* at several locations across the state.

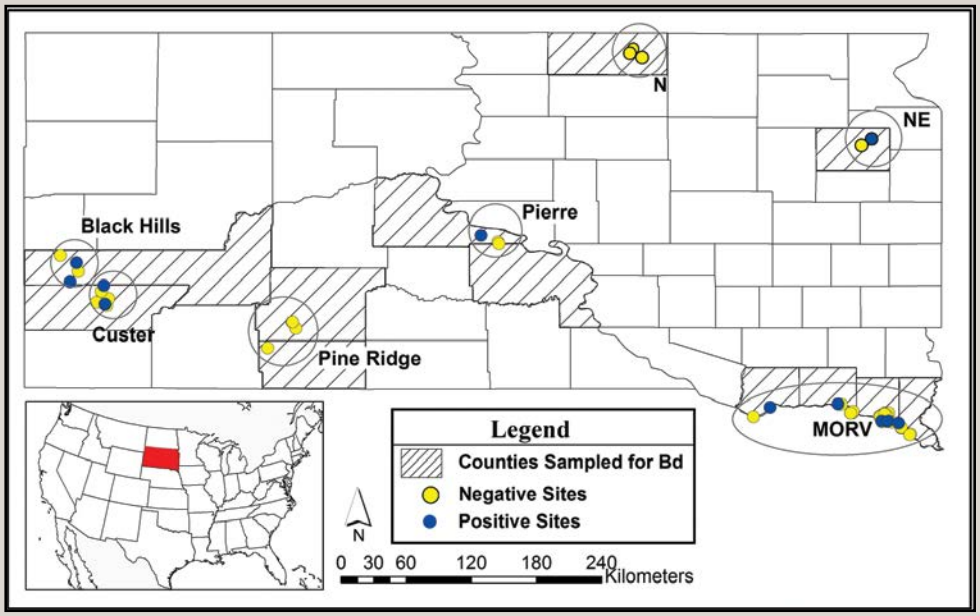

Fig. 1. Locations sampled for *Batrachochytrium dendrobatidis* (*Bd*) within South Dakota, USA. Blue dots represent sites with *Bd* detections.

We opportunistically sampled amphibians for *Bd* in seven regions of South Dakota (Fig. 1) from April 2010–August 2011. Using nylon swabs, amphibians were rubbed along the ventral side of their hands, feet, legs and abdomen five times each for a total of 25 swipes per amphibian. To prevent cross contamination, animals were handled and swabbed separately, and swabs were stored individually in tubes. Samples were kept on ice until brought to a molecular biology facility at the University of South Dakota where they were kept at 0°C until processed.

DNA was extracted from swabs using the included protocol for DNeasy® spin column kits (Qiagen, Inc., Germantown, Maryland). Each sample was run using an Applied Biosystems StepOne Plus quantitative PCR machine (Applied Biosystems, Inc., California) according to the fast qPCR protocol as described by Kerby et al. (2013). Each sample was run in triplicate and was considered positive if at least two of the three replicates were positive. A negative control was placed on each plate and the *Bd* standards utilized were from CSIRO laboratories in Australia. The pathogen load estimates are provided in zoospore genome equivalents per swab.

TABLE 1. Infection status and pathogen load (# zoospores/positive swab) of species by each region sampled. Fractions represent the number of infected/tested. Average pathogen load estimates for positive values are provided in parentheses. MRV- Missouri River Valley in southeastern part of the state; N- Northern region; NE- Northeastern region; Pierre- Pierre National Grasslands; Black Hills- Black Hills National Forest; Pine Ridge- Pine Ridge Reservation; Custer- Custer State Park.

Species	MRV	N	NE	Pierre	Black Hills	Pine Ridge	Custer	Total	
Lithobates blairi	1/428 (0.48)	0/3	1/28 (0.04)	0/34	2/62 (2.29)	0/9	7/37 (8.15)	11/599 (5.4)	1.80%
Lithobates pipiens	0/55	-	-	-	-	-	-	0/55	0%
Anaxyrus woodhousii	3/343 (2.28)	-	-	-	-	-	0/1	3/344 (2.28)	1%
Acris crepitans	2/102 (110)	-	-	-	-	-	-	2/102 (110)	2%
Pseudacris maculata	68/249 (638)	-	-	1/12 (0.1)	1/30 (0.15)	-	-	70/291	24%
Hyla chrysoscelis/versicolor	0/53	-	-	-	-	-	-	0/53	0%
Spea bombifrons	-	-	-	-	-	0/15	0/1	0/16	0%
Ambystoma tigrinum	0/6	-	-	-	-	0/6	-	0/12	0%
Anaxyrus cognatus	4/100 (0.35)	-	-	-	-	-	-	4/100 (0.35)	4%
Anaxyrus hemiophrys	-	0/2	-	-	-	-	-	0/2	0%
Total by region	7/1287 (535)	0/6	1/28 (0.04)	1/46 (0.11)	3/90 (1.58)	0/30	7/39 (8.15)	90/1525 (470)	5.9%

A total of 1525 amphibians of 10 species were swabbed for *Bd* during the study (Fig. 1). *Bd* was detected on 90 animals (6%) in five different species, and in 5/7 regions sampled (Table 1). One site had particularly high *Bd* occurrence, with 64 of 68 *Pseudacris maculata* being *Bd*-positive near Vermillion, South Dakota. There was no mortality observed at this site, nor were any symptomatic individuals detected.

As expected, *Bd* was present in most of our sampled sites in South Dakota. We found *Bd* in half the species examined, and in all regions with > 30 samples taken. *Bd* was not detected in two sampled regions, but this might be due to lower sampling (< 30) at these sites. Similarly, the three species for which *Bd* was not detected also had low sample sizes, perhaps precluding an accurate assessment if *Bd* occurs at a low level in these species (Skerratt et al. 2008). Therefore the results cannot be examined as a comprehensive determination of host or pathogen distribution, but our findings provide important information regarding infection on specific species and sites.

Acknowledgments.—We thank our field crew, in addition to the field assistance from several biologists across the state. Samples were received from D. Swanson, S. Martin, R. Mars, A. Kiesow, S. Miller, B. Smith, M. Miller, P. Lynch, and A. Higa; and field sampling was aided by R. Verheul, E. Weisser, T. Snyders, K. Wert, C. Duhon, and D. Quist. This research was supported by funding from a Wildlife Action Plan grant from South Dakota Fish, Game and Parks, and qPCR was performed on instrumentation obtained from NSF funding MRI-0923419.

Amphibian Chytrid Fungus in Woodhouse's Toads, Plains Leopard Frogs, and American Bullfrogs along the Platte River, Nebraska, USA

We recently documented the first published record of the fungal pathogen *Batrachochytrium dendrobatidis* (chytrid) in Nebraska, USA, where we detected a high prevalence of chytrid in American Bullfrogs (*Lithobates catesbeianus*) in off-channel aquatic habitats on an island of the Platte River (Harner et al. 2011). This pathogen causes the disease chytridiomycosis (Longcore et al. 1999), and widespread amphibian mortality from infection is contributing to declines and regional extirpation of amphibians worldwide (Berger et al. 1998; Collins 2010; Daszak et al. 1999; Lips et al. 2006). We were concerned by the high prevalence of chytrid in American Bullfrogs on this island because American Bullfrogs have been introduced to the region (Fogell 2010), and they may negatively affect native amphibians through both direct (e.g., predation) and indirect (e.g., competition, disease transmission) interactions. Loss of native amphibians is of conservation concern for a number of reasons, notably the loss of biodiversity (e.g., Collins 2010) and alterations to ecosystem structure and function (Whiles et al. 2006). Along the Platte River, amphibian declines also have potentially negative consequences for an endangered migratory bird, the Whooping Crane (*Grus americana*), which relies on the river and surrounding wetlands for critical habitat during spring and autumnal migrations (USFWS 1978) and preys upon frogs during migratory stops (Geluso et al., *in press*).

Objectives of our study were to spatially extend sampling for chytrid to other sites and species along the central Platte River. In our prior survey we also sampled native Plains Leopard Frogs (*Lithobates blairi*) and Woodhouse's Toads (*Anaxyrus woodhousii*) and did not detect chytrid, but our sample sizes were low (N = 20 and 21, respectively) and from a small geographical area, so we may have failed to detect infection (Skerratt et al. 2008). Therefore, in this survey we focused on obtaining sample sizes of greater than 40 individuals for each species and sampled several locations to determine whether chytrid was present in native species and at multiple locations along the central Platte River in Nebraska.

We sampled amphibians along a 100-km reach of the Platte River in central Nebraska (Fig. 1) on Jeffrey Island (40.6901°N, 99.5956°W) and Cottonwood Ranch (40.6868°N, 99.4784°W) in Dawson County; Blue Hole East (40.6836°N, 99.3758°W) in Kearney County; Dippel (40.7036°N, 98.7950°W) in Buffalo County; and Shoemaker Island (40.7920°N, 98.4620°W) in Hall County. Property ownership was as follows: Jeffrey Island (Central Nebraska Public Power and Irrigation District), Cottonwood Ranch and Blue Hole East (Nebraska Public Power District), and Dippel and Shoemaker Island (The Crane Trust). Sampling effort was more extensive on Jeffrey Island to compare this more western portion of the river reach to the previously sampled Shoemaker Island (Harner et al. 2011).

Amphibians were sampled from a variety of habitats including river channels, sloughs (natural and created), ponds, borrow pits, stock tanks, and uplands. Sampling occurred in autumn 2011 (Shoemaker Island) and spring-summer 2012 (all sites).

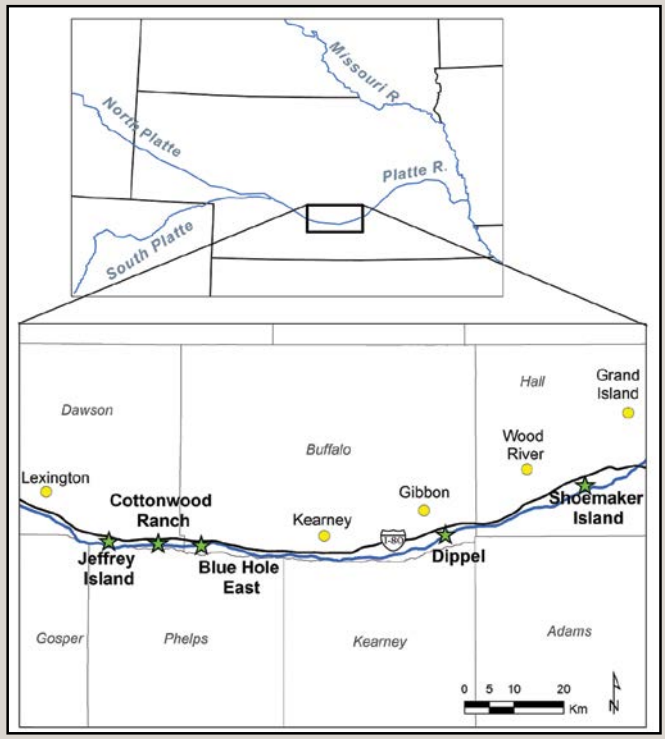

FIG. 1. Location of sites sampled (denoted by green stars and bold text) for amphibian chytrid fungus, *Batrachochytrium dendrobatidis*, along the Platte River in central Nebraska, USA. Detailed image also includes county names (italics), select towns (yellow circles), the Platte River (blue line), and interstate highway (dark black line).

Individuals were captured by hand, and researchers wore disposable gloves to minimize contamination and changed gloves between each capture. After capture we rubbed a sterile swab (Fisherfinest® Dry Transport Swab; Fisher HealthCare, USA) across the abdomen, throat, inner thighs, webbing of toes, and mouthparts. Swabs were air-dried, stored frozen, and shipped frozen to the University of South Dakota for testing.

Samples were analyzed for chytrid with real-time Taqman PCR assay. DNA was extracted from swabs using Qiagen DNEasy Blood and Tissue spin column kits according to manufacturer's protocol. Pathogen load per swab was determined with quantitative PCR on a StepOnePlus machine (Applied Biosystems). Reactions were run based on a standard protocol described in Kerby et al. (2013). Each plate contained a standardized dilution

series of quantified zoospore numbers to use as a standard curve. A negative control also was included on every plate. Samples were run in triplicate, and positive values were averaged to determine a final estimated pathogen load for each swab.

The study area experienced prolonged drought in 2012 with an onset of abnormally dry conditions by late May that transitioned to extreme drought by the end of August (droughtmonitor.unl.edu; accessed 30 November 2012). As a result, virtually no temporary ponds were present, hindering our ability capture any Plains Spadefoots (*Spea bombifrons*) and restricting our captures of Boreal Chorus Frogs (*Pseudacris maculata*) to only three. Both species rely on temporary ponds and both are known from the region (Ballinger et al. 2010, Fogell 2010).

Table 1. *Batrachochytrium dendrobatidis* (*Bd*) prevalence (no. *Bd*-positive individuals/total no. individuals sampled) at sites along the central Platte River, Nebraska, USA.

Date	Site	Woodhouse's Toad	American Bullfrog	Plains Leopard Frog

	Cottonwood Ranch	4/14	0/3	3/14
Aug 2012	Jeffrey Island	—	1/12	0/2
	Blue Hole	0/2	—	—
	TOTAL	14/40 (35%)	10/55 (18%)	26/66 (39%)

We sampled a total of 163 individuals of four species for chytrid (Table 1). Five Plains Leopard Frogs were sampled from Shoemaker Island on 25 October 2011 prior to winter, whereas all other individuals were sampled from 9 May to 21 August 2012. Four Plains Leopard Frogs were metamorphs, and all other individuals were adults.

Across sites, prevalence of chytrid was 35% for Woodhouse's Toads, 18% for American Bullfrogs, and 39% for Plains Leopard Frogs (Table 1). None of the Boreal Chorus Frogs tested positive. One Plains Leopard Frog metamorph tested positive. For positive samples, the pathogen load (number of zoospore equivalents per swab) ranged from 0.87-6560 (median = 51) in Woodhouse's Toads; 0.02-84 (median = 2) in American Bullfrogs; and 0.04-8139 (median = 27) in Plains Leopard Frogs.

Our findings add to the geographical extent and list of species infected by chytrid in central Nebraska along the Platte River. Results confirm presence of chytrid in invasive American Bullfrogs as well as in two native species, Woodhouse's Toads and Plains Leopard Frogs, across this 100-km reach of river. Prevalence of chytrid was moderate (30%) across species sampled, but pathogen load did not exceed levels reported as a threshold for mass mortality in other species (~ 10,000 zoospore equivalents per swab; Vredenburg et al. 2010). Prevalence of chytrid was lower in American Bullfrogs from Shoemaker Island in this study (25%) compared to our 2010 survey (41%; Harner et al. 2011). This difference may be linked to climatic differences between years, as 2010 had above-average precipitation (4th wettest over 74-year record), whereas 2012 had below-average precipitation (4th driest over 74-year record) measured at Grand Island, NE (www.ncdc.noaa.gov; accessed 30 November 2012). The influence of drought on chytridiomycosis is currently debated, but some argue that dry conditions may decrease prevalence and severity of chytrid (Kriger 2009). Regardless, presence of chytrid in invasive American Bullfrogs is a concern because they are nonclinical carriers of chytrid (Daszak et al. 2004; Garner et al. 2006; Schloegel et al. 2009).

Seasonality of chytrid infection was not a focus of this study, but trends emerged that warrant further investigation. Prevalence of chytrid in Plains Leopard Frogs from Shoemaker Island went from 1 in 5 to 4 in 5 individuals between autumn and spring, and prevalence of chytrid was higher in May than subsequent months in 2012 across sites. These trends potentially suggest that Plains Leopard Frogs may be at an elevated risk in spring. Other studies have observed peaks in chytrid prevalence and pathogen load in early spring (Gaertner et al. 2012; Kriger and Hero 2007a; Retallick et al. 2004), as well as a negative relationship between temperature and chytrid prevalence (e.g., Kriger and Hero 2007a). From a conservation standpoint, availability and abundance of Plains Leopard Frogs in March and April may be important for foraging Whooping Crane during migratory stopovers in the region (Geluso et al., *in press*).

There is need for ongoing monitoring of chytrid along the central Platte River to capture variation across habitats as well as through time. Along with the seasonal patterns noted above, we saw a trend of varying incidences of infection among different habitats (data not presented due to small sample size), though more systematic sampling is required to draw inferences about prevalence among different habitats. Other studies have detected an effect of local environmental conditions on chytrid, such as greater prevalence in permanent compared to ephemeral water bodies (Kriger and Hero 2007b). A better understanding of the seasonality and influence of habitat on the pathogen may help resource managers target conservation measures to reduce the threat of chytrid to native amphibians along the central Platte River, and thus help maintain the natural structure of the interconnected aquatic and terrestrial food webs along these flood plains.

Acknowledgments.—We thank Central Nebraska Public Power and Irrigation District (CNPPID) and the Crane Trust for funding; Mark Peyton (CNPPID) and Jim Jenniges (Nebraska Public Power District) for providing information about and access to the western study sites; the laboratory of Jacob Kerby at the University of South Dakota for conducting analyses; Keith Geluso for comments on an earlier version of the manuscript; and Alexandra Frohberg, Jamie Jones, Liz McCue, Evan Suhr, and Angelina Wright for assistance with sampling. Amphibians were studied under authorization of the Nebraska Game and Parks Commission (Scientific and Educational Permit issued to Keith Geluso).

Amphibian Populations in Brazos River Basin, Texas, Show No Evidence of *Bd* Infection

Discovered and described only a decade ago (Longcore et al. 1999), amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) has rapidly expanded its range, and new geographic distribution reports are being added frequently (http://www.bd-maps.net/). In the United States, *Bd* infection has been documented in amphibian populations in nearly all of the states (Olson et al. 2013). However, except for two studies, the state of Texas remains under-surveyed for this pathogen. Gaertner et al. (2009) reported *Bd* occurrence in individuals of five salamander species along parts of the Colorado and Guadalupe River basins in Central Texas. Saenz et al. (2010) reported incidences of *Bd* infection in five anuran and one plethodontid species *s*pread across forested areas in Eastern Texas. To address the lack of surveys in the Brazos River basin of Texas, we sampled amphibians for *Bd* from two disjunct areas along the watershed (Fig. 1).

In August–September 2011 and April–May 2012 we sampled from urban modified playa wetlands within the city of Lubbock, located in northwest Texas near the upper reaches of the Brazos River basin. Lake Waco wetlands, situated in the central portion of the Brazos River basin in central Texas, were sampled in May–July 2012. Areas of study were under severe drought in the year 2011. However, sampling in 2012 for Lubbock and Lake Waco wetlands (sampled only in 2012) was carried out earlier in the year when temperatures were cooler and rain events facilitated breeding aggregations.

Post-metamorphic amphibians were swabbed 20–25 times along the ventral side of their abdomen, legs, and between their toes following established field protocol (Brem et al. 2007). Additionally, we also took scrapes from tadpole mouthparts using wooden toothpicks (procedure described by Retallick et al. 2006) while sampling in 2011 as very few post-metamorphic amphibians were being observed in Lubbock during this year. Amphibians were swabbed during call/visual surveys conducted following rain events and tadpole mouthparts were scraped during dipnet surveys conducted during the day in the following two weeks.

Overall, we sampled 76 individuals from Lubbock and 51 individuals from Lake Waco wetlands comprising a total of ten anuran and one caudate species (Table 1). Collected swabs and scrapes were stored in 70% ethanol (Brem et al. 2007) and placed in temperatures at or below –20°C until further analysis. Because swabs were stored in cold temperatures there was no danger of degradation (Hyatt et al. 2007; K. Kriger, pers. comm.). In March 2013, swabs and scrapes from Lubbock, pooled by species, location, and year, were sent to Pisces Molecular LLC in Boulder, Colorado. Total DNA was extracted from all samples using a spin-column DNA purification procedure; these were then assayed for the presence of *Bd* by a modified version of the procedure described by Annis et al. (2004) which increases sensitivity and specificity for *Bd* detection at the laboratory (J. Wood, pers. comm.). Each PCR run included the following controls: positive DNA-DNA prepared from a laboratory culture of *Bd* Strain JEL 270, negative DNA-DNA prepared from an uninfected amphibian, no DNA (control)-water in place of template DNA (information from this paragraph has been directly adapted from test results for the PCR assay from Pisces laboratory).

Samples from Waco were tested for the presence of *Bd* at Texas Tech University in Lubbock using the DNA extraction method and subsequent polymerase chain reaction protocol described by Annis et al. (2004). Samples were pooled in groups of ten, and DNA was extracted using the PrepMan Ultra reagent according to supplier protocol (Life Technologies, Grand Island, New York). We then used the *Bd*-specific primers Bd1a and Bd2a to amplify any *Bd* DNA present from the samples. In addition, we also ran a positive control containing *Bd* genomic DNA and a negative control containing sterile water only. Following PCR analysis, we ran the products on a 1.2% agarose gel and included a 1 kb DNA ladder in order to determine the size of any amplified products. GelStar nucleic acid gel stain (Cambrex Bio Science Rockland, Inc. Rockland, Maine) was used to visualize bands.

Overall, we collected 76 swabs (including tadpole mouthpart scrapes) from Lubbock and 51 swabs from Lake Waco wetlands. All 127 swabs tested negative for the presence of *Bd*. Because our sample size safely exceeds that recommended by Skerratt et al. (2008) for achieving 95% certainty, we can reasonably infer that *Bd* infection has either not spread into, or remains exceedingly rare, in urban wetlands in Lubbock and the Lake Waco wetlands of the Brazos River basin despite reported incidences of *Bd* infection in adjacent river basins to the south and east (Gaertner et al. 2009; Saenz et al. 2010) (Fig. 1).

We acknowledge that the occurrence of false-negatives is a possibility. The year 2011 was a period of intense drought in the region, with Lubbock and Waco setting new records for minimum precipitation and high temperatures. June–August 2011 were the warmest three months ever recorded in the region: the 100-day streak of 32.2+ degree days at Lubbock finally ended on 3 September 2011, while Waco saw a similar streak of 44

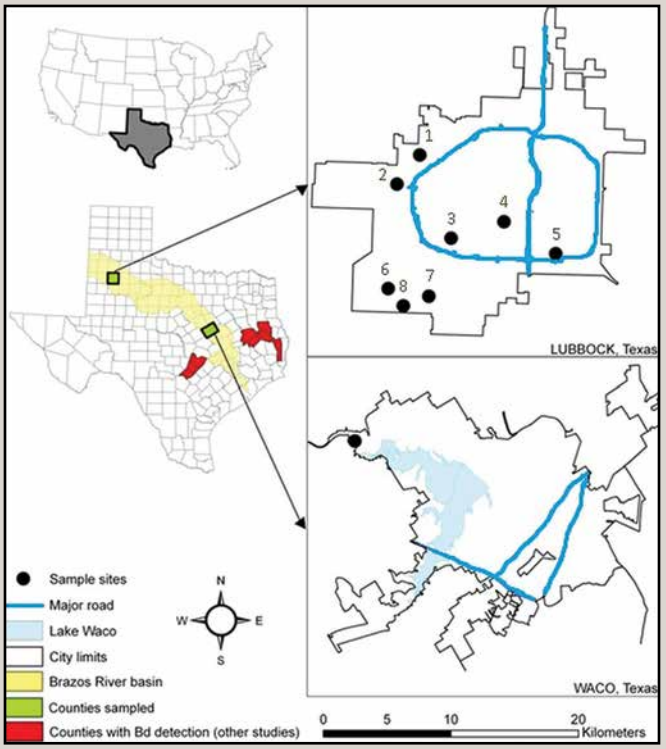

FIG. 1. *Batrachochytrium dendrobatidis* sampling locations at Lubbock and Waco, Texas, USA. Both cities lie in disjunct portions of the Brazos River basin.

days ending on 12 August 2011 (NOAA 2011, 2012). The unprecedented drought and high temperatures, clearly detrimental to amphibian activity and reproduction (Ramesh et al. 2012), may have ironically contributed to keeping *Bd* at bay (Kriger 2009). *Bd* grows best, has a better chance of spread, and is more likely to survive as zoospores in cool, wet conditions and in permanent water bodies (Gaertner et al. 2012; Johnson et al. 2003; Kriger and Hero 2007a). Moreover, *Bd* zoospores are highly prone to desiccation (Johnson et al. 2003), and occur at higher levels in permanent versus ephemeral water bodies (Gaertner et al. 2012; Kriger and Hero 2007b). Lack of standing water for long periods combined with prolonged temperatures well above 30°C during this period could have resulted in the lack of *Bd* occurrence in 2011 and into 2012.

Sampling for this study was conducted over two years in Lubbock and one year in Waco. It would have been ideal to sample under "normal" conditions considering the seasonality associated with chytrid fungus prevalence and persistence. However, such a "normal" year is unlikely in the near future of Texas where climate projections depict increased extreme temperatures, heat waves, and prolonged droughts along with decreased precipitation. Under such circumstances amphibian populations may already be vulnerable, and one cannot discount the additional influence of *Bd* (if present). We suggest that continuous monitoring for *Bd* presence be conducted in the long-term to catch the spread of this deadly pathogen in the state irrespective of climatic conditions.

Acknowledgments.—We are extremely grateful to The Center for Forest Sustainability at Auburn University for their financial support. This project was largely possible because of the invaluable field assistance afforded by V. Viswanathan, J. Lippert, U. Kawai, J. Kissner,

High Prevalence of Ranavirus Infection in Permanent Constructed Wetlands in Eastern Kentucky, USA

Amphibians are declining globally, and both land-use change and infectious diseases are major drivers (Miller et al. 2011; Stuart et al. 2004). Because most wetlands have been destroyed or altered throughout the United States (e.g., Kentucky has lost >81% of its historic wetlands; Dahl 2000), wetlands have been created for mitigation or wildlife management (Brown and Richter 2012; Dahl 2000). Hundreds of closely spaced permanent wetlands have been constructed on ridge tops in eastern Kentucky for wildlife management within the same landscape as natural, ephemeral wetlands (Brown and Richter 2012). Although constructed wetlands provide breeding habitat for amphibians, they might not replace the function of natural wetlands, supporting different amphibian communities than natural ponds (Denton and Richter 2013; Drayer 2011). Moreover, constructed ponds have been associated with ranavirus outbreaks (Harp and Petranka 2006; Petranka et al. 2007). Our objective was to test for the occurrence of ranavirus and amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), in amphibian populations inhabiting natural and constructed ridge-top wetlands of eastern Kentucky, USA.

Field surveys were conducted in five constructed and one natural ridge-top wetland located in the Daniel Boone National Forest (DBNF), Kentucky. All boots, dipnets, and other field supplies were disinfected with a 1% solution of Nolvasan® to prevent spread of pathogens between sampling sites (Bryan et al. 2009). Dipnet sampling was used to capture up to 10 adult Eastern Newts (*Notopthalmus viridescens*) in each constructed wetland and 10 Wood Frog (*Lithobates sylvaticus*) larvae in the natural wetland from 21 to 27 May 2012 (Table 1). No Eastern Newts were detected in natural wetlands, and no Wood Frog larvae were detected in constructed wetlands. These species were chosen because they have been associated with ranaviral disease die-offs in eastern North America (Green et al. 2002; Greer et al. 2005; Harp and Petranka 2006). None of the individuals that were collected had signs of ranaviral disease (Miller et al. 2011). Each Eastern Newt was swabbed using a BBL™ CultureSwab™ (Beckton, Dickinson, and Company, Franklin Lakes, New Jersey, USA) and had a 10-mm portion of its tail clipped. Swabs and tail clips were stored in 70% ethanol. Each *L. sylvaticus* larva was euthanized in 10% ethanol and stored in 95% ethanol (EKU Institutional Animal Care and Use Committee; protocol #04-2012).

Ranavirus and *Bd* testing was performed at the University of Tennessee Center for Wildlife Health following published standardized procedures (Hoverman et al. 2011a; Souza et al. 2012). Genomic DNA (gDNA) was extracted from a homogenate of liver and kidney tissue (Wood Frogs), tail clips (Eastern Newts), and swabs (Eastern Newts) using a commercially available kit (DNeasy Blood and Tissue Kit, Qiagen Inc., Valencia, California, USA) with molecular-grade water as the extraction control. We measured the concentration of gDNA in each sample and standardized the amount of gDNA (0.25 µg) used for PCR among samples. Quantitative real-time PCR (i.e., TaqMan® PCR) was performed following Boyle et al. (2004) for *Bd* assays and following Picco et al. (2007) for ranavirus assays. Positive controls were similar for each assay, and included DNA extracted from culture and a positive animal for each pathogen. Negative controls included molecular-grade water and DNA extracted from an animal that was known to be negative for each pathogen. Each assay was run for 40 cycles on an ABI 7900 Fast Real-Time PCR System (Life Technologies Corporation, Carlsbad, California, USA). Each sample was run in duplicate and considered positive only if the PCR cycle threshold (CT) was < 30 for both samples. The CT value was determined by developing a standard curve for our PCR equipment using serial dilutions of known pathogen quantities. When samples were positive, we used the standard curve to predict virus concentration (i.e., plaque forming units, PFU) using the average CT for the sample.

We did not detect *Bd* in any samples; however, nine samples from two constructed wetlands were positive for ranavirus

infection (prevalence = 70% and 33%; Table 1). Eight of nine positive samples had titers < 100 PFU and the other had a titer of 4114 PFU. The lower titers are consistent with these newts being sublethally infected (Miller and Gray, unpubl. data). From our controlled research (e.g., Hoverman et al. 2011a), individuals with titers > 4000 PFU frequently develop ranaviral disease (Miller and Gray, unpubl. data). Given that adult newts are known to move among wetlands in close proximity (Porej et al. 2004) and use ephemeral and permanent wetlands (Hunsinger and Lannoo 2005), it is possible that this species could transport ranavirus overland among sites similar to Tiger Salamanders (*Ambystoma tigrinum*, Brunner et al. 2004) into amphibian communities composed of highly susceptible species (e.g., Wood Frogs; Hoverman et al. 2011a). The role of Eastern Newts in the epidemiology of ranavirus needs greater attention.

While our sample sizes do not allow for meaningful comparisons of ranavirus prevalence between natural and constructed wetlands, there are several reasons we think that constructed ponds might have important consequences for ranavirus epidemiology. First, the constructed wetlands where ranavirus was detected are permanent compared to the ephemeral hydroperiod (< 200 days) of natural wetlands in the ecosystem. Because ranavirus virions are inactivated faster in dry soil compared to water (Nazir et al. 2012), the long hydroperiods might increase the persistence of ranavirus outside the host. Second, constructed wetlands tend to have deeper littoral zones, which might be important sites for ectotherms to warm body temperatures and inactivate pathogens (Raffel et al. 2010). The absence of *Bd* in the constructed wetlands might be attributed to lack of substrate complexity and shade (Raffel et al. 2010), or it could be because *Bd* has not arrived to the ecosystem or was simply not detected. Lastly, the constructed wetlands were inhabited by amphibian species that require a longer hydroperiod for development and may function as reservoirs for ranavirus, including Eastern Newts, American Bullfrogs (*L. catesbeianus*), and Green Frogs (*L. clamitans*; Daszak et al. 2004; Gahl et al. 2012; Hoverman et al. 2011b).

Ranavirus has been previously documented in two wetlands in Kentucky (J. MacGregor, Kentucky Department of Fish and Wildlife Resources, pers. comm.). We recommend more intensive studies in the future that examine a larger geographic area and larger sample size per wetland type. Additionally, post-metamorphic stages should be tested to determine if terrestrial stages of amphibians are important reservoirs as hypothesized by Brunner et al. (2004).

Acknowledgments.—We thank the Department of Biological Sciences at Eastern Kentucky University (EKU) for use of field vehicles and equipment, Daniel Douglas for field assistance, Jennifer Tucker for laboratory assistance, and Tom Biebighauser, Richard Hunter, and Ben Miller of the U.S. Forest Service for logistical guidance and field assistance. Funding was provided by a EKU University Funded Scholarship Grant. Research was approved by EKU's Institutional Animal Care and Use Committee (protocol #04-2012).

Low Prevalence or Apparent Absence of *Batrachochytrium dendrobatidis* Infection in Amphibians from Sites in Vietnam and Cambodia

Batrachochytrium dendrobatidis (*Bd*), the causative agent for the amphibian disease chytridiomycosis, is widespread, but patchily distributed throughout Asia. Within Asia, *Bd* has so far been detected from amphibians in Cambodia, China, India, Indonesia, Japan, Kyrgyzstan, Laos, Malaysia, the Philippines, South Korea, Sri Lanka, and Vietnam (Bai et al. 2010; Goka et al. 2009; Kaiser and Grafe 2012; Kusrini et al. 2008; Mendoza II. et al. 2011; Nair et al. 2011; Savage et al. 2011; Swei et al. 2011; Vörös et al. 2012; Wei et al. 2010; Yang et al. 2009). The pattern of *Bd* prevalence in Asia appears drastically different to that in Australia, Africa, the Americas, and Europe, with isolated cases and low infection prevalence (or apparent absence) at most sites (Swei et al. 2011). To date, there have been no reports of *Bd*-associated morbidity or mortality and no evidence of enigmatic amphibian population declines in Southeast Asia (Rowley et al. 2010).

Bd was first reported to occur in Vietnam in 2011, with seven samples taken in 2008 from Bidoup-Nui Ba National Park, Lam Dong Province, testing positive for *Bd* (Swei et al. 2011). To date, these are the only positive records published for Vietnam. Here we carried out an additional survey for *Bd* at Bidoup-Nui Ba National Park, and performed surveys at localities in central and southern Vietnam, and in adjacent eastern Cambodia (Fig. 1; Table 1).

Amphibians were sampled for *Bd* as part of broader amphibian surveys in evergreen forest areas between May 2009 and July 2010. During nocturnal surveys, conducted along rocky streams and adjacent evergreen forest, adult amphibians were captured by hand and placed in individual plastic bags. Immediately after capture, or the following morning (<8 h after collection), the ventral surface of each frog was swabbed using

TABLE 1. Locations and taxonomic breadth of amphibians sampled for *Batrachochytrium dendrobatidis* (*Bd*) in Cambodia and Vietnam.

Country	Site	Location	Elevation (m)	No. Families	No. Genera	Approx. No. Species
Cambodia	Seima	12.32°N, 107.10°E	485–585	7	11	16
Vietnam	Bidoup-Nui Ba	12.18°N, 108.68°E	1470–1625	5	10	15
	Ngoc Linh	15.22°N, 107.73°E	1085–2300	5	15	27
		15.06°N, 107.86°E	935–2105	5	12	15

Total		500

a sterile cotton swab (Medical Wire & Equipment, Potley, UK). Due to taxonomic uncertainty and the presence of undiagnosed diversity within the amphibians of the area, only the generic identity of the individuals swabbed is given (Table 2).

Samples were stored in the field at ambient temperatures (below that known to reduce the amount of *Bd* detectable; Van Sluys et al. 2008) for 5–14 days, and then at approximately –20°C for 3 weeks to 4 months prior to analysis. Storage conditions are unlikely to have affected our results, as storing swabs for 18 months at 4°C, 23°C, and –20°C does not reduce the amount of *Bd* detected (Hyatt et al. 2007). Due to the cost of PCR and our previous negative results (Swei et al. 2011), our 2009 samples from three sites were analyzed in batches of up to 8 samples via PCR (full volume or half volume pooling; Table 3). Samples from 2010 were analyzed individually via qPCR (Table 3).

All samples were analyzed by Pisces Molecular (Boulder, Colorado, USA). Samples pooled by full volume were transferred into a 50-ml tube of ethanol and vortexed to dislodge any zoospores from the swabs before pooling. Samples pooled by half volume had 1.1 ml of 70% ethanol added to the sample tubes and 500µl was transferred into a 15 ml screw-capped centrifuge tube for each pool. Individually analyzed samples had 1.0 ml of 70% ethanol added before mixing by vortexing, and then the entire volume was transferred into a clean microfuge tube. Total DNA was extracted from all samples using Qiagen DNeasy tissue kits. Samples were evaluated for the presence of *Bd* using diagnostic PCR (Annis et al. 2004), modified for greater specificity and sensitivity at Pisces Molecular. Samples were assayed in triplicate and each PCR run included three controls: a positive control (*Bd* DNA), negative control (sample from an uninfected amphibian), and No DNA control (remains uncapped during addition of sample DNA to detect contaminating DNA in the PCR reagents or carryover of positive DNA during reaction set-up). PCR results were scored as very strong positive (equivalent to the positive control), strong positive, positive, weak positive and negative (no signal/below the limit of detection). Each qPCR run included positive controls of *Bd* DNA in serial ten-fold dilutions from 3×10^6 to 3×100 molecules per reaction (used to generate the standard curve). Each qPCR run also included a No DNA control (as above). The detection sensitivity of these assays is three target sequence molecules (~0.02 zoospore equivalents).

TABLE 3. *Batrachochytrium dendrobatidis* (*Bd*) infecting amphibians in Cambodia and Vietnam. Prevalence and lower and upper 95% binomial confidence limits (CL; singlicate) or bias-corrected maximum likelihood estimates (MLE) for *Bd* infection from samples analyzed using diagnostic PCR.

Country	Site	Date	Analysis	N	Prevalence	95% CL/MLE Lower	95% CL/MLE Upper
Cambodia	Seima	July/August 2009	PCR; Pooled (full volume)	100	0.00	0.00	3.62
Vietnam	Bidoup Nui-Ba	July 2010	qPCR singlicate	124	0.00	0.00	3.39
	Ngoc Linh	July 2009	PCR; Pooled (full volume)	133	3.29	1.08	7.86
		March/April 2010	qPCR; singlicate	43	0.00	0.00	19.51
	Nui Ong	May 2009	PCR; Pooled (half volume)	100	0.00	0.00	3.62

For individually analyzed samples, we calculated the lower and upper 95% binomial confidence limits of infection prevalence. For pooled samples, we calculated infection prevalence and lower and upper confidence intervals using a bias-corrected maximum likelihood estimation for pooled samples of unequal sample size (Hepworth 2005), using PooledInfRate 4.0 (Biggerstaff 2009).

A total of 500 skin swab samples from at least 52 species of amphibian was analyzed for *Bd*. Only samples from the July 2009 survey of Ngoc Linh tested positive for *Bd* using diagnostic PCR (Table 3). Four of the 18 pooled samples collected from the site in 2009 tested strong positive, giving an overall estimate of 3.29% infection prevalence and maximum likelihood estimates of confidence intervals of 1.08–7.86%. Follow-up surveys at Ngoc Linh during 2010 failed to detect *Bd* at the site, with a maximum likelihood estimate of upper confidence interval of 19.51%. Because samples were not pooled by species, the identity of infected species could not be determined. However, positive pools included sampled from the families Megophryidae (*Leptobrachium, Leptolalax, Ophryophryne, Xenophrys*), Microhylidae (*Microhyla*), Ranidae (*Odorrana*) and Rhacophoridae (*Gracixalus, Kurixalus, Rhacophorus*). Samples from the three survey sites at which *Bd* was not detected had upper limits of infection prevalence ranging from 3.39–7.86%. We did not detect *Bd* on samples from Bidoup-Nui Ba, a site at which we previously detected *Bd* at low prevalence and at low intensity of infection in 2008 (6.36% "low" infection prevalence in May 2008 [7/110]), but failed to detect *Bd* again in March 2008 (0/155) (Swei et al. 2011).

Our results are consistent with a previous, large-scale survey of Asia, which found a surprisingly low *Bd* prevalence throughout Asia (2.35%; Swei et al. 2011). Surveys at many sites in the region have failed to detect *Bd*, despite often relatively large sample sizes including Ratanakiri Province, Cambodia (0/178); Lao Cai Province, Vietnam(0/82); Savannahkhet, Laos (0/191), Hong Kong (0/274), and Thailand (0/123) (Rowley et al. 2007; McLeod et al. 2008; Swei et al. 2011). Recent surveys of captive native frogs in the trade markets in Cambodia, Laos, Singapore, and Vietnam also reported low infection prevalence, with <1% (14/2389) of amphibians testing weakly positive for *Bd* (Gilbert et al. 2013).

Although most surveys for *Bd* in Asia have reported low prevalence or apparent absence, *Bd* has been reported at high infection prevalence at some sites (Yang et al. 2009; Swei et al. 2011), including four sites in Cambodia, where *Bd* was reportedly detected on 41% (59/144) of swab samples from southwestern Cambodia (Mendoza et al. 2011), and on 36% (86/238) of swab samples at three lowland sites in Cambodia (Gaertner et al. 2011). These survey results are in contrast to our survey at Seima and our previous surveys in eastern Cambodia, which did not detect the pathogen (Swei et al. 2011). Differences in the habitat and the amphibian species sampled makes comparisons between surveys difficult. However, Mendoza et al. (2011) and Gaertner et al. (2011) surveyed a very different suite of amphibians (most of which were lowland, pond-breeding amphibians).

The global distribution (Olson et al. 2013) and emergence of *Bd* remains far from clarified, and recent evidence suggests that *Bd* may have evolved from or at least have a long history in Asia (Goka et al. 2009; Bai et al. 2012). Additional disease surveys in Asia, molecular analysis of *Bd* from throughout Asia, and infection trials to assess disease susceptibility in Asian amphibians are required in order to assess the threat of *Bd* to amphibians in Asia. We also recommend assessing the identity and distribution of *Bd* haplotypes present throughout Asia. Given that qPCR appears unable to detect all strains of *Bd* present in Asia (Goka et al. 2009), it may also be necessary to identify the *Bd* haplotypes present at a site in order to assess the accuracy of *Bd* infection prevalence estimates obtained using qPCR.

Acknowledgments.—The Vietnamese Ministry of Agriculture and Rural Development and staff at Bidoup-Nui Ba National Park, Ngoc Linh Nature Reserve, and Nui Ong Nature Reserve kindly facilitated surveys and issued permission to collect (Permit numbers 3023/GTBNN-KL, 1430/GT-BNN-KL, 776/BNN-KL, 748/BNN-KL). The People's Committee of Kon Tum Province issued permit number 548/UBND-DN for JJLR for work in the province. H.E Ty Sokun provided field survey permission for Seima Biodiversity Conservation area and WCS Cambodia greatly facilitated fieldwork. This work was supported by the ADM Capital Foundation, Ocean Park Conservation Foundation Hong Kong, the John D. and Catherine T. MacArthur Foundation and the Lawrence Foundation. Cao Tien Kien, Phung Thi Huong, Nguyen Hoang Vu, Huynh Tan Hop, Da Du Ha Tien, Vu Hanh Dung, Ta Van Thuc, Pham Xuan Nguyen, Le Van Khanh, Nguyen Quoc Hung, Le Thi Thanh Ngan, A Phuoc, A Tru, A Nap, A Doi, Chad Minshew, and Eleanor Appleby assisted in the field. For all this assistance we are most grateful.

Wei, Y., K. Xu, D.-Z. Zhu, X.-F. Chen, and X.-L. Wang. 2010. Early-spring survey for *Batrachochytrium dendrobatidis* in wild *Rana dybowskii* in Heilongjiang Province, China. Dis. Aquat. Org. 92:241–244.

Yang, H, H. Baek, R. Speare, R. Webb, S. Park, T. Kim, K. C. Lasater, S. Shin, S. Son, J. Park, M. Min, Y. Kim, K. Na, H. Lee, and S. Park. 2009. First detection of the amphibian chytrid fungus *Batrachochytrium dendrobatidis* in free-ranging populations of amphibians on mainland Asia: survey in South Korea. Dis. Aquat. Org. 86:9–13.

GEOGRAPHIC DISTRIBUTION

CAUDATA — SALAMANDERS

***AMBYSTOMA MACULATUM* (Spotted Salamander)**. USA: MICHIGAN: Clare Co.: Neithercut Woodland, located near trail marker 139 (43.865263°N, 84.935862°W; WGS84) 26 June 2012. Katherine Belknap, Bradley J. Swanson. Verified by Angela M. Riedel. Museum of Natural History, Central Michigan University (MCNH 2013.004: LS-18a–LS-35a). New county record (Holman 2012. The Amphibians and Reptiles of Michigan: A Quaternary and Recent Faunal Adventure. Wayne State University Press, Detroit, Michigan. 528 pp.). Extends the range of *A. maculatum* 50 km NW from Mecosta Co.

Individuals were identified to species by sequencing 800 bp mtDNA d-loop and cytochrome b loci (18 individuals; Bi and Bogart 2010. BMC Evol. Biol. 10:238). Larvae were caught with nets in a leafy temporary pond in hardwood forest, sampled for DNA, and immediately released.

Field work supported by Central Michigan University and ATCG laboratory. Scientific Collector's Permit Issued 1 May 2012/ Michigan DNR, Central Michigan University IACUC Approval #12-18, 26 June 2012.

KATHERINE BELKNAP, Central Michigan University, 152 Brooks Hall, 200 Library Drive, Mount Pleasant, Michigan 48858, USA; e-mail: belkn1ka@cmich.edu.

***AMBYSTOMA TALPOIDEUM* (Mole Salamander)**. USA: FLORIDA: Hamilton Co.: Suwannee Ridge Mitigation Park Wildlife and Environmental Area, 4.5 km E jct County Road 249 and County Road 751 (30.4437°N, 83.0479°W; WGS84). 28 March 2013. Kevin M. Enge. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 169958, color photo). First county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). Larva captured while dipnetting a sinkhole pond in sandhill habitat. A second specimen was photographed (UF 169959) at a second location in Hamilton Co.

KEVIN M. ENGE (e-mail: kevin.enge@myfwc.com) and **PAUL E. MOLER**, Florida Fish and Wildlife Conservation Commission, 1105 S.W. Williston Road, Gainesville, Florida 32601, USA.

***BOLITOGLOSSA SALVINII* (Salvin's Mushroom-tongued Salamander)**. EL SALVADOR: CUSCATLÁN: Municipality of Cojutepeque: Cerro Las Pavas, Canton El Carrizal (13.709774°N, 88.938550°W; WGS 84), 820 m elev. 31 August 2012. Esmeralda Martinez Umaña. Verified by Eric N. Smith. KUDA 012272–73. New department record (Köhler et al. 2006. The Amphibians and Reptiles of El Salvador. Krieger Publ. Co., Malabar, Florida. ix + 238 pp.), extending the species' range ca. 25 km ENE from the only other known Salvadoran locality at Instituto Tropical de Investigaciones Científicas, San Salvador. The salamander was caught and released after photographs were taken by a farmer in a banana plantation surrounded by coffee groves and remnants of tropical broadleaf submontane semideciduous forest**.** The area is now almost completely deforested and replaced by housing developments and agricultural fields. Because the species was last collected in El Salvador over 50 years ago and since west-central El Salvador lacks natural vegetation, Greenbaum and Komar (2010. *In* Wilson et al. [eds.], Conservation of Mesoamerican Amphibians and Reptiles, pp. 436–459. Eagle Mountain Publ., LC, Eagle Mountain, Utah) speculated that the species was already extirpated from the country, but our record indicates that its ability to survive in banana plantations may sustain the species until proper conservation actions can be initiated.

VLADLEN HENRÍQUEZ, Colonia Bello San Juan, Calle Madrid, Pol 11. #7, San Salvador, El Salvador (e-mail: vladhen_21@hotmail.com); **ELI GREENBAUM**, Department of Biological Sciences, The University of Texas at El Paso, 500 W. University Ave., El Paso, Texas 79968, USA (e-mail: egreenbaum2@utep.edu).

***NOTOPHTHALMUS VIRIDESCENS* (Eastern Newt)**. USA: MISSOURI: Madison Co.: Fredericktown. Pond located 50 m E of Piney Creek on private land (37.563564°N, 90.413417°W; WGS84). 14 April 2013. Abbigail E. Nicholson. Verified by Dustin. S. Siegel. University of Missouri-Columbia (UMC 2348P). New county record. Fills the gap among the surrounding Bollinger, Iron, St. Francois, and Wayne counties (Edmond and Daniel 2013 [updated 5 April 2013]. Missouri Herpetological Atlas Project. Available at http://atlas.moherp.org/; accessed 14 April 2012). Found in fishless pond.

ABBIGAIL E. NICHOLSON, Department of Biology, Southeast Missouri State University, Cape Girardeau, Missouri 63701, USA; e-mail: aenicholson1s@semo.edu.

***NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS* (Central Newt)**. USA: FLORIDA: Hamilton Co.: Suwannee Ridge Mitigation Park Wildlife and Environmental Area, 4.5 km E jct County Road 249 and County Road 751 (30.4437°N, 83.0479°W; WGS84). 28 March 2013. Paul E. Moler. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 169988, color photo). First vouchered record for the county (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). Collected sexual pair of paedomorphs while dipnetting a sinkhole pond in sandhill habitat.

KEVIN M. ENGE (e-mail: kevin.enge@myfwc.com) and **PAUL E. MOLER**, Florida Fish and Wildlife Conservation Commission, 1105 S.W. Williston Road, Gainesville, Florida 32601, USA.

***PSEUDOEURYCEA CAFETALERA* (Coffee Grove Salamander)**. MÉXICO: PUEBLA: Municipality of Chichiquila: El Cantil, Río Tenejapa (19.206889°N, 97.052611°W; WGS84), 1467 m elev. 24 April 2010. Andrés Alberto Mendoza Hernández. Verified by Edmundo Pérez Ramos. MZFC 26528. First record for the state, extending its known range ca. 7 km (airline) WNW of Las Cañadas,

Municipality of Huatusco, Veracruz (Parra-Olea et al. 2010. Zootaxa 2725:57–68). The salamander was found in an ecotone between cloud forest and tropical evergreen forest.

ISRAEL SOLANO ZAVALETA (e-mail: crotalus.viper@gmail.com), **LUIS CANSECO MÁRQUEZ** (e-mail: lcanseco@gmail.com), **ANDRÉS ALBERTO MENDOZA HERNÁNDEZ** (e-mail: andreasmeher@gmail.com), and **LUIS FELIPE VÁZQUEZ VEGA** (e-mail: lepatula@hotmail.com), Museo de Zoología, Facultad de Ciencias, UNAM, A.P. 70-399, México D.F. 04510, México.

***SIREN LACERTINA* (Greater Siren)**. USA: VIRGINIA: York Co.: Yorktown Naval Weapons Station, 4.8 km WSW Yorktown (37.229192°N, 76.565914°W; WGS 84). 10 April 2013. J. C. Mitchell and L. H. Eiser. Verified by Kenneth L. Krysko. Florida Museum of Natural History (FLMNH 169851). New county record (Mitchell and Reay. 1999. Atlas of Amphibians and Reptiles in Virginia. Virginia Dept. of Game and Inland Fisheries, Richmond, Virginia. Spec. Publ. 1. 122 pp.). Fills hiatus between known locations 35 km to the SSE in Isle of Wight Co. and 92 km to the northwest in King and Queen Co. both of which are in the Atlantic Coastal Plain. One individual with 40 costal grooves was caught in a minnow trap and released in an isolated ephemeral pond surrounded by mixed hardwoods and Loblolly Pine (*Pinus taedus*).

Field work was in support of Naval Facilities Engineering Command Contract No. N62470-08-D-1008, Task Order No. WE41. VDGIF Threatened/Endangered Species Permit No. 047472.

JOSEPH C. MITCHELL, P.O. Box 2520, High Springs, Florida 32655, USA (e-mail: dr.joe.mitchell@gmail.com); **LINDSAY H. EISER**, 1900 S. Sunset Street, Suite 1-F, Longmont, Colorado 80501, USA (e-mail: lindsay.eiser@tetratech.com).

ANURA — FROGS

AMEEREGA HAHNELI. BOLIVIA: BENI DEPARTMENT: Moxos Province: East of Municipality of San Ignacio de Moxos (14.724444°S, 65.0023056°W, WGS84; 153 m elev.). 2 May 2009. Steven Poe and Eric Schaad. Museum of Southwestern Biology at the University of New Mexico (MSB 94808) and Colección Boliviana de Fauna CBF-6661). This species was previously known from the Amazonian lowlands from Colombia, eastern Ecuador, Peru, Guiana, Brazil, and northwestern Bolivia. Within Bolivia this species is known from the Beni, La Paz, and Pando departments, and has been expected to occur in Moxos Province (De la Riva et al. 2000. Rev. Esp. Herpetol. 14:19–164; Kohler 2000. Amphibian Diversity in Bolivia. A Study with Special Reference to Montane Forest Regions. Bonn. Zool. Monogr. 48, 243 pp.). Here we report the first record of this species from the Moxos Province approximately 438 km from the western edge of *A. hahneli*'s previously known range from José Ballivian Province. The fieldwork for this project was funded by NSF DEB-0844624 to Steven Poe.

MASON J. RYAN (e-mail: mjryan@unm.edu), **STEVEN POE, ERIC SCHAAD**, Department of Biology and Museum of Southwestern Biology, University of New Mexico, Albuquerque, New Mexico 87131-0001, USA; **ALVARO J. AGUILAR-KIRIGIN**, Investigador Asociado, Área de Herpetología, Colección Boliviana de Fauna, Casilla 8706, Campus Universitario de Cota Cota, Calle 27 s/n, Universidad Mayor de San Andrés, La Paz, Bolivia. Edificio: Facultad de Ciencias Puras y Naturales (e-mail: aguilarkirigin@yahoo.es).

CRAUGASTOR LAEVISSIMUS. HONDURAS: OLANCHANO: Muralla National Park (15.09710521°N; 86.73783487°W; WGS84) 1466 m elev. 10 October 2010. Mason Ryan, Steven Poe, Ian M. Latella, and Julian Davis. Verified by Jay M. Savage. MCZ A-140226. First record of this species within Muralla National Park; the closest record is from ca. 50 km west of the park (McCranie and Wilson 2002. The Amphibians of Honduras. SSAR Contrib. Herpetol. 19:i–x, 1–625). The female was discovered in the leaf litter along a small stream in mid-elevation cloud forest. This is also an important find because the species is designated as Endangered by IUCN Red List of Threatened Species, Version 2011.2 (www.iucnredlist.org) and because highland populations above 900 m elevation in Honduras were considered to have disappeared (McCranie and Wilson 2002, *op. cit.*). Fieldwork for this project was funded by NSF DEB-0844624 to S. Poe.

MASON J. RYAN (e-mail: mjryan@unm.edu), **STEVEN POE**, **IAN M. LATELLA**, and **JULIAN DAVIS**, Department of Biology and Museum of Southwestern Biology, University of New Mexico, Albuquerque, New Mexico 87131-0001, USA.

CROSSODACTYLUS CARAMASCHII. BRAZIL: PARANÁ: Municipality of Guaraqueçaba: Reserva Natural Salto Morato (25.1666°S, 48.2892°W, datum WGS84; 310–535 elev.). 24 February – 1 March 2013. T. M. Iapp. Museu Nacional, Rio de Janeiro (MNRJ 85774–85777, 85780, 85782). 11 April 2013. F. B. Oliveira (MNRJ 85778–85779, 86781). All verified by J. P. Pombal Jr.. All previous records of the species are for the southern portion of the state of São Paulo: Apiaí and Iporanga (Araujo et al. 2010. Biota Neotrop. 10[4]:257–274); Cotia (Dixo and Verdade 2006. Biota Neotrop. 6[2]:1–20); Parque Estadual Carlos Botelho (Forlani et al. 2010. Biota Neotrop. 10[3]:265–309), Iguape (Zina et al. 2012. Biota Neotrop. 12[1]:251–260), and Eldorado (Bastos and Pombal 1995. Copeia 1995[2]:436–439). First state record and the southernmost for the species, extending its distribution 148 km SE from Eldorado (Bastos and Pombal, *op. cit.*), the nearest locality previously cited.

MANUELA SANTOS-PEREIRA, **FREDERICO BATISTELLA DE OLIVEIRA**, **CARLOS FREDERICO DUARTE ROCHA**, Departamento de Ecologia, Universidade do Estado do Rio de Janeiro, Rua São Francisco Xavier 524, Maracanã, 20550-011, Rio de Janeiro, RJ, Brazil; **TCHEILY MIRIELE IAPP**, Universidade Regional Integrada do Alto Uruguai e das Missões, Avenida Sete de Setembro 1628, 99700-000, Erechim, RS, Brazil.

***DENDROPSOPHUS MICROCEPHALUS* (Small-headed Treefrog; Rana Trepadora Amarilla)**. HONDURAS: LA PAZ: Potrerillos (14.292983°N, 87.7068°W; WGS84), 920 m elev. 8 April 2012. Alexander Gutsche and James R. McCranie. Verified by Steve W. Gotte. USNM 580448. First record for La Paz, with the closest known locality ca. 35 km WNW near Jesus de Otoro, Intibucá (McCranie 2006. Smithson. Herpetol. Info. Serv. 137:1–39). The frog was active at night on a leaf of a small tree at the edge of a small stream in a pasture carved from premontane dry forest (Holdridge 1967. Life Zone Ecology, rev. ed. Trop. Sci. Center, San José, Costa Rica. 206 pp.).

TESTUDINES — TURTLES

***CHELYDRA SERPENTINA* (Snapping Turtle)**. USA: INDIANA: Howard Co.: Howard Township, 4709 Pavilion Court (40.494148°N, 86.063365°W; WGS 84). 25 May 2012. Michael S. Finkler. Verified by Robert Brodman. Indiana State Museum (INSM 71.7.0524). New county record (Minton 2001. Amphibians & Reptiles of Indiana, 2nd ed. Indiana Academy of Science, Indianapolis. 404 pp.). Eggs collected from nest adjacent to pond and incubated to hatching (voucher specimen hatched 2 August 2012).

MICHAEL S. FINKLER, School of Sciences, Indiana University Kokomo, PO Box 9003, Kokomo, Indiana 46901, USA; e-mail mfinkler@iuk.edu.

***CHELYDRA SERPENTINA* (Snapping Turtle)**. USA: TENNESSEE: Lauderdale Co.: Chickasaw National Wildlife Refuge (35.874421°N, 89.643653°W; NAD 83). 5 April 2013. James P. Flaherty and Michael Fulbright. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19409 photo voucher). New county record (Scott and Redmond 2008 [updated 15 February 2013]. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/reptatlas/ [accessed 6 May 2013]). Nearest record ca. 38 km E in Crockett Co. Hatchling captured in dipnet near bank of vegetated slough.

JAMES P. FLAHERTY, **MICHAEL C. FULBRIGHT**, and **C. M. GIENGER**, Center of Excellence for Field Biology/Department of Biology, Austin Peay State University, Clarksville, Tennessee 37040, USA (e-mail: jflaherty1@my.apsu.edu).

***CHRYSEMYS DORSALIS* (Southern Painted Turtle)**. USA: TENNESSEE: Lauderdale Co.: Chickasaw National Wildlife Refuge (35.874526°N, 89.643346°W; NAD 83). 5 April 2013. James P. Flaherty and Michael Fulbright. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19411 [photo voucher]). New county record (Scott and Redmond 2008 [updated 15 February 2013]. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/reptatlas/ [accessed 6 May 2013]). Nearest confirmed record ca. 59 km SE in Haywood Co. Two individuals observed basking on a floating log in vegetated slough.

JAMES P. FLAHERTY, **MICHAEL C. FULBRIGHT**, and **C. M. GIENGER**, Center of Excellence for Field Biology/Department of Biology, Austin Peay State University, Clarksville, Tennessee 37040, USA (e-mail: jflaherty1@my.apsu.edu).

***TERRAPENE NELSONI* (Spotted Box Turtle)**. MEXICO: JALISCO: Municipality of Ameca: Sierra de Quila, near Tecolotlán, 100 km SW of Guadalajara (20.4016°N, 104.122°W; WGS84), 2020 m elev. 6 August 2000. John Pint. Verified by Jacobo Reyes-Velasco. UTADC 7639. First municipality record, extending range 32 km S from its closest reported locality near Guachinango, Jalisco, although the coordinates provided by Buskirk and Ponce-Campos (2011. Chelon. Res. Monogr. [5]:060.1–060.9) for that distance were inaccurate when compared to our measures. The turtle was active during the day in an oak forest disturbed to a certain extent by agricultural fields.

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider)**. USA: INDIANA: Howard Co.: Kokomo, 101 W. Boulevard (40.462213°N, 86.131553°W; WGS 84). 6 June 2012. David W. Johnson and Michael S. Finkler. Verified by Robert Brodman. Indiana State Museum (INSM 71.7.0525). New county record (Minton 2001. Amphibians & Reptiles of Indiana, 2nd ed. Indiana Academy of Science, Indianapolis. 404 pp.). Eggs collected from nest on stream embankment and incubated to hatching (voucher specimen hatched 8 August 2012).

MICHAEL S. FINKLER, School of Sciences, Indiana University Kokomo, PO Box 9003, Kokomo, Indiana 46901, USA; e-mail mfinkler@iuk.edu.

SQUAMATA — LIZARDS

***ANOLIS DISSIMILIS*.** BRAZIL: ACRE: Senador Guiomard, Fazenda Experimental Catuaba (10.082222°S, 67.625833°W; datum WGS84), elev. 183 m, in open forest with bamboo (*Guadua weberbaueri*). 16 March 2013. P. R. Melo Sampaio, J. M. L. Maciel, A. da Silva, M. Nogueira, S. Matos, L. Matos, and J. C. da Silva. Verified by M. B. Souza. Herpetological Collection Universidade Federal do Acre, Rio Branco (UFAC-0075). Species previously known only from type locality: Ituahuania, Departamento Madre de Dios, Peru (Williams 1965. Breviora [233]:1–15). First country record, extends the known distribution ca. 490 km N from type locality.

PAULO ROBERTO MELO-SAMPAIO (e-mail: prmelosampaio@gmail.com), **BRUNO LUIZ ALENCAR DE SOUZA MELO**, Universidade Federal do Acre Laboratório de Herpetologia (HerPet) Campus Universitário CEP:69.915-900 Rio Branco, AC – Brazil; **ALEX DA SILVA**, **JÚNIOR MARCOS LIMA MACIEL**, **MARIANA NOGUEIRA**, **SIMONE MATOS DE ARRUDA**, **LARISSA LIMA**, **JOSIMAR COSTA DA SILVA**, and **LUCICLÉIA MATOS**, União Educacional do Norte – Uninorte Alameda Hungria, 200, Jardim Europa II - CEP: 69.911-900 Rio Branco, AC – Brazil.

***ANOLIS NEBULOSUS* (Clouded Anole)**. MEXICO: JALISCO: Municipality of Cañadas de Obregón: Temacapulín, 88 km NE of Guadalajara (21.17772°N, 102.709083°W; WGS84), 1771 m elev. 14 March 2010. Jesús M. Rodríguez-Canseco, Krystal L. González-Estupiñán, and Luand E. López-Rodríguez. Verified by Jacobo Reyes Velasco. UTADC 7609, 7610. First municipality record, and a range extension of 72 km S from localities in southern Aguascalientes (Vázquez Díaz and Quintero Díaz 2005. Anfibios y Reptiles de Aguascalientes. CONABIO, CIEMA A.C., México D.F. 318 pp.) and 102 km E of Atolinga, Zacatecas (Ahumada-Carrillo 2010. Herpetofauna del Municipio de Atolinga, Zacatecas. Thesis, Cent. Univ. Cienc. Biol. Agro., Univ. de Guadalajara. Zapopan,

Jalisco. 82 pp.). One of the lizards was found active on an oak tree (*Quercus laeta*) in one of the remaining patches of oak forest in the area, while the other was found crawling on rocks in direct sunlight within a grove of cedar trees (*Juniperus coahuilensis*).

JESÚS MAURICIO RODRÍGUEZ-CANSECO (e-mail: jmrc2603@hotmail.com), **KRYSTAL LUCÍA GONZÁLEZ-ESTUPIÑÁN** (e-mail: krystal_mclean@hotmail.com), and **LUAND ELIUD LÓPEZ-RODRÍGUEZ** (e-mail: luandaja@hotmail.com), Centro Universitario de Ciencias Biológicas y Agropecuarias, Universidad de Guadalajara, Zapopan, Jalisco, 45110, México.

***ANOLIS (= NOROPS) SAGREI* (Brown Anole)**. USA: TEXAS: Nacogdoches Co.: 220 N. Stallings Drive (31.391105°N, 94.393109°W; WGS84). 17 September 2012. Daniel Saenz. Verified by Toby J. Hibbitts. Biodiversity Research and Teaching Collection, Texas A&M University, TCWC 96834. New county record (Dixon 2013. Amphibians and Reptiles of Texas, 3rd ed., Texas A&M University Press, College Station. 447 pp.). An adult male *A. sagrei* was first observed displaying in the lawn and garden section of the Lowe's store in Nacogdoches, Texas on 15 September 2012. The voucher specimen was collected two days later at the same store and at least four other adult lizards were observed on the outdoor plant displays; however, *A. sagrei* is not known from any other locations in Nacogdoches. The nearest records for *A. sagrei* are from Brazos Co, over 200 km SW of this locality, and from Harris Co., over 225 km S of Nacogdoches. Many of the tropical plants at the Lowe's store are shipped from Florida. Thus, it is likely that the lizards are new introductions from Florida, via the tropical plant trade, rather than a range expansion in Texas.

DANIEL SAENZ (e-mail: dsaenz@fs.fed.us), **JOSH B. PIERCE**, **JAMES D. CHILDRESS**, and **CORY K. ADAMS**, Wildlife Habitat and Silviculture Laboratory, Southern Research Station, U.S.D.A. Forest Service, Nacogdoches, Texas 75965, USA; **APRIL A. GRADY**, Nacogdoches High School, Nacogdoches, Texas 75965, USA.

***BACHIA GUIANENSIS* (Guyana Bachia)**. COLOMBIA: GUAVIARE: San José del Guaviare, vereda El Retiro, balneario La Pedrera, Puente de Piedra (2.541467°N, 72.722532°W; datum Bogotá WGS 84). 23 October 2012. G. F. Medina-Rangel. Colección de Reptiles, Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Bogotá (ICN 12275); San José del Guaviare, vereda La Pizarra, Puerta de Orión, forest (2.510672°N, 72.706790°W; datum Bogotá WGS 84). 26 October 2012. M. L. Calderón. (ICN 12270). Both verified by G. Cárdenas-Arévalo. This lizard was only known from Colombia in the department of Vichada, corregimiento de Santa Rosa in the Natural National Park El Tuparro (locality Centro Alto Tuparro) and department of Guainía in municipality of Inírida, and Venezuela in the Territorio Federal of the Amazonas state in Río Guapuchi, tributary of Río Ventuari (Hoogmoed and Dixon 1977. Zool. Med. 51:25–31; Gorzula and Señaris 1999. Contribution to the Herpetofauna of the Venezuelan Guayana I: A Data Base. Scientia Guaianae, Caracas, No. 8, 269 pp.; Ávila-Pires 2005. *In* Hollowell and Reynolds [eds.], Checklist of the Terrestrial Vertebrates of the Guiana Shield. Bull. Biol. Soc. Washington 13:25–42; Uetz 2012. TIGR Reptile Database (version Oct 2007). *In* Bisby et al. [eds.]. Species 2000 and ITIS Catalogue of Life, version 2012. <www.catalogueoflife.org/col/>; Rivaset al. 2012. Zootaxa 3211:1–64). First state record, extending the range ca. 565 km from the nearest known population (type locality: Guri, Bolivar state, Venezuela; Hoogmoed and Dixon, *op. cit.*; Uetz, *op. cit.*; Rivas et al., *op. cit.*).

GUIDO F. MEDINA-RANGEL (e-mail: gfmedinar@unal.edu.co), and **MARTHA L. CALDERÓN** (e-mail: mlcalderone@unal.edu.co), Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Apartado Aéreo 7495, Bogotá D.C., Colombia.

***CELESTUS ENNEGRAMMUS* (Huaxteca Lesser Galliwasp)**. MEXICO: CHIAPAS: Municipality of Berriozabal: 2–3 km NNE Tierra y Libertad (16.86033°N, 93.33675°W; WGS84), 1180 m elev. 22 September 2012. Israel Solano Zavaleta. Verified by Edmundo Pérez Ramos. MZFC 27272. First record for the state, extending the known range ca. 137 km (airline) E of the nearest locality at La Gloria, Oaxaca (Campbell and Camarillo 1994. Herpetologica 50:193–209). The lizard was found in tropical evergreen forest.

ISRAEL SOLANO ZAVALETA (e-mail: crotalus.viper@gmail.com), **LUIS CANSECO MÁRQUEZ** (e-mail: lcanseco@gmail.com), and **ERIC CENTENERO ALCALA** (e-mail: eca_46@hotmail.com), Museo de Zoología, Facultad de Ciencias, UNAM, A.P. 70-399, México D.F. 04510, México.

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko)**. USA: CALIFORNIA: Los Angeles Co.: San Fernando Valley, Chatsworth (34.250946°N; 118.608146°W; WGS 84; elev. 286 m). Seven individuals representing adult (N = 4) and juvenile (N = 3) age classes and both sexes were collected in a residential community on stucco or stone walls or stone mailbox posts exposed to direct exterior illumination from 2100–2230 h, 14 and 16 August 2010. R. W. Bernstein, W. L. Bernstein, A. Lopez, and Z. M. Lopez. CSUN 3475 (additional specimens are alive in captivity at CSUN). Verified by R. E. Espinoza. New county records. Originally submitted as photo vouchers to the Natural History Museum of Los Angeles County (LACM) Lost Lizards of Los Angeles citizen science project (http://www.nhm.org/site/activities-programs/citizen-science/lost-lizards-project; LACM photographic vouchers PC 1633–1634). Extends the range ca. 195 km WNW (airline) from the closest vouchered localities at Palm Springs, Riverside Co., California (LACM 147938, 152671, 179871–76). In Southern California, *H. turcicus* has also become established at one or more localities in the counties of Imperial, San Bernardino, and San Diego (Beaman et al. 2005 Herpetol. Rev. 36:79). Although we observed at least 10 additional specimens within a two-block radius of the residential area from which these geckos were collected, surveys outside of this region produced no further sightings suggesting a very limited distribution and relatively recent introduction. Several residents in the area independently suggested that they first noticed the geckos approximately 10 years ago. Repeated visits (2010–13) to the neighborhood by us and herpetologists and staff from California State University, Northridge and LACM indicate the population is thriving, but not expanding.

WILLIAM L. BERNSTEIN (e-mail: wb@tridian.com) and **REESE W. BERNSTEIN**, P.O. Box 7922, Northridge, California 91327, USA.

***LEIOCEPHALUS CARINATUS* (Northern Curly-tailed Lizard)**. USA: FLORIDA: Polk Co.: Lakeland, near West Pipkin Road and Yates Road (27.97473°N, 82.01237°W; WGS84; coordinate uncertainty: 1250 m; elev. 40 m). 7 March 2013. Cathy Knott. Verified by Kevin M. Enge. Florida Museum of Natural History (UF 169952). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final Report, Project Agreement 08013, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). A single individual was collected in a residential garage south of the Lakeland Linder Regional Airport. Extends the range ca. 63 km SW of the closest known verified voucher (UF 165483) from the Gaylord Palms Resort and Convention Center, 6000 West Osceola Parkway, Kissimmee, Osceola Co.

LAURENCE L. CONNOR, Florida Fish and Wildlife Conservation Commission, 601 West Woodward Avenue, Eustis, Florida 32726, USA (e-mail: larry.connor@myfwc.com); **KENNETH L. KRYSKO**, Division of Herpetology, Florida Museum of Natural History, 1659 Museum Road, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@ufl.edu); **CATHY KNOTT**, University of South Florida, Florida Industrial and Phosphate Research Institute, 1855 West Main Street, Bartow, Florida 33830, USA (e-mail: cknott@admin.usf.edu).

***LEPIDOPHYMA GAIGEAE* (Gaige's Tropical Night Lizard)**. MEXICO: SAN LUIS POTOSÍ: Municipality of Aquismón: Cascada de Tamúl (21.802821°N, 99.179946°W; WGS84), 220 m elev. 2 January 2010. Iván T. Ahumada-Carrillo. Verified by Jacobo Reyes Velasco. UTADC 7504–7505. First municipality record and first vouchered state record. Lemos-Espinal and Dixon (2013. Amphibians and Reptiles of San Luis Potosí. Eagle Mountain Publ., Eagle Mountain, Utah. xii + 300 pp.) mapped and listed localities for the species from the municipalities of Huehuetlán, San Vicente Tancuayalab, and Zaragoza, but gave no reference to voucher specimens. Municipality of Aquismón is located directly adjacent to Huehuetlán, and Cascadada de Tamúl represents the lowest reported elevation for the species, as all others were from above 700 m (Bezy and Camarillo R. 2002. Contr. Sci. Nat. Hist. Mus. Los Angeles Co. [493]:1–41). The lizard was found inside a rock crevice in subtropical dry forest, in contrast to pine-oak forest, the normal habitat for this species (Lemos-Espinal and Dixon, *op. cit.*).

IVÁN T. AHUMADA-CARRILLO, Centro Universitario de Ciencias Biológicas y Agropecuarias, Universidad de Guadalajara, Carretera a Nogales Km. 15.5, Las Agujas, Nextipac, Zapopan, Jalisco, México; e-mail: lepidus320@hotmail.com.

***PLESTIODON LATICEPS* (Broad-headed Skink)**. USA: MISSOURI: Madison Co.: Fredericktown, eastern border of Piney Creek (37.562952°N, 90.412876°W; WGS84). 11 May 2013. Abbigail E. Nicholson. Verified by Dustin S. Siegel. University of Missouri-Columbia (UMC 2350P). New county record. This record fills the gap between the bordering St. Francois and Wayne counties (Edmond and Daniel 2013 [updated 5 April 2013]. Missouri Herpetological Atlas Project. Available at http://atlas.moherp.org/; accessed 11 May 2013).

Laboratory, University Park, Pennsylvania 16802, USA (e-mail: szg170@psu.edu).

***LAMPROPELTIS TRIANGULUM* (Milksnake)**. USA: MISSOURI: Madison Co.: Fredericktown (37.562794°N, 90.413135°W; WGS84). 25 May 2013. Abbigail E. Nicholson. Verified by Dustin S. Siegel. University of Missouri-Columbia (UMC 2354P). New county record. This record fills the gap within the surrounding Bollinger, Iron, and Wayne counties (Edmond and Daniel 2013 [updated 5 April 2013]. Missouri Herpetological Atlas Project. Available at http://atlas.moherp.org/; accessed 25 May 2013).

ABBIGAIL E. NICHOLSON, Department of Biology, Southeast Missouri State University, Cape Girardeau, Missouri 63701, USA; e-mail: aenicholson1s@semo.edu.

***LEPTOPHIS MEXICANUS* (Mexican Parrot Snake; Ranera Mexicana)**. HONDURAS: LA PAZ: Potrerillos (14.292983°N, 87.7068°W; WGS84), 920 m elev. 9 April 2012. Alexander Gutsche and James R. McCranie. Verified by Steve W. Gotte. USNM 580445. First record for La Paz, with the closest known locality ca. 15 km N at Lo de Reina, Comayagua (McCranie 2011. The Snakes of Honduras. Systematics, Distribution, and Conservation. SSAR Contrib. Herpetol. 26:x + 714 pp.). The snake was active in a tree during midmorning on a sunny day ca. 2.5 m above a small river in secondary premontane dry forest (Holdridge 1967. Life Zone Ecology, rev. ed. Trop. Sci. Center, San José, Costa Rica. 206 pp.).

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **ALEXANDER GUTSCHE**, Museum für Naturkunde, Herpetologie, Leibniz-Institut für Evolutions- und Biodiversitätsforschung, Invalidenstr. 43, D-10115 Berlin, Germany (e-mail: alexander.gutsche@mfn-berlin.de).

***OPHEODRYS AESTIVUS* (Rough Green Snake)**. USA: TENNESSEE: Van Buren Co.: Gorge Scenic Drive near Millikan's Overlook, Fall Creek Falls State Park (35.67982°N, 85.36717°W; WGS 84). 11 May 2013. S. Graham, C. Thawley, and G. McCormick. Verified by David Laurencio, AUM AHAP-D 675 (digital photograph file). New county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. http://www.apsu.edu/reptatlas (updated 30 May 2013; accessed 1 June 2013). Specimen found dead on road. Records of *Opheodry aestivus* are sparse in the Cumberland Plateau, and this record fills a distributional gap between the nearest records approximately 60 km W in Cannon Co., 48 km N in Putnam Co., and 42 km SE in Rhea Co.

Funding for this research was provided by IOS-1051367 to T. Langkilde.

CHRISTOPHER J. THAWLEY (e-mail: cthawley@gmail.com), **GAIL L. MCCORMICK** (e-mail: glm173@psu.edu), and **SEAN P. GRAHAM** (e-mail: szg170@psu.edu), Department of Biology, Pennsylvania State University, 208 Mueller Laboratory, University Park, Pennsylvania 16802, USA.

***RAMPHOTYPHLOPS BRAMINUS* (Brahminy Blindsnake)**. USA: ARIZONA: Maricopa Co.: private residence near major crossroads, Greenway and 7th Street, Phoenix (33.62903°N, 112.060439°W; NAD 83). 16 May 2010. Susan Sferra. Verified by Van Wallach. MCZ R-189083. First voucher from an established Arizona population. Nearest records are from Hildalgo County, Texas to the east (Merino et al. 2009. Herpetol. Rev. 40:366), Hermosillo, Sonora, Mexico to the south (Quijada-Mascareñas and Enderson 2007. Herpetol. Rev. 38:490), and San Diego Co., California to the west (Palmer and Fisher 2010. Herpetol. Rev. 41:518). Specimen collected alive under small wooden board in backyard covering a sparsely vegetated area of Bermuda Grass (*Cynodon* spp.) adjacent to bare ground interspersed with Hopbush (*Dodonaea viscosa*), Sweet Acacia *(Acacia farnesiana*), and dried vegetative debris under dry conditions. The residence is 1.6 km from a local nursery. Collector had purchased and planted vegetation from this nursery on several occasions.

Previous specimens were collected at this location on 11 November 2007 and 1 December 2007 by Susan Sferra. These specimens were identified by Michael J. Sredl, Arizona Game and Fish Department, but were not independently verified or accessioned into museum collections. All were observed after heavy rains. A second vouchered specimen (UAZ 57402-PSV) was collected at the same location on 23 December 2010.

Additional *Rhamphotyphlops braminus* specimens have been collected in the region but there is not sufficient evidence that these represent established populations: 33.308629°N, 111.810242°W, 20 October 2008, Cathy Kasevich (unvouchered); 33.410968°N, 111.970299°W, 6 November 2007, Philip C. Rosen. Verified by G. L. Bradley (UAZ 56919).

The parthenogenetic Brahminy Blindsnake is the first nonnative snake to become established in Arizona and is generally considered to be the most widespread, globally distributed, snake species in the world.

We thank Andrew Holycross for his assistance.

New Geographic Distribution Records for Reptiles from North Carolina, USA

The geographic distribution of reptiles in North Carolina (USA) was summarized by Palmer and Braswell (1995) and has since been supplemented by others, including Beane (1998), Beane and Palmer (2006), Eskew et al. (2008), and Beane and Corey (2010). Here I report additional new records based upon specimens and photographs verified by William M. Palmer or Bryan L. Stuart and housed at the North Carolina State Museum of Natural Sciences (NCSM). Geocoordinates are based on datum WGS 84.

TESTUDINES — TURTLES

APALONE SPINIFERA ASPERA **(Gulf Coast Spiny Softshell)**. Richmond Co.: 10.3 km W Rockingham, Pee Dee River (34.9433302°N, 79.868541°W). 9 May 2002. Wayne C. Starnes. NCSM 62966. First specimen voucher for county. Palmer and Braswell (1995) reported a photographic record.

JEFFREY C. BEANE
North Carolina State Museum of Natural Sciences, Research Laboratory, 1626 Mail Service Center, Raleigh, North Carolina 27699-1626, USA
e-mail: jeff.beane@naturalsciences.org

CHELYDRA SERPENTINA **(Snapping Turtle)**. Catawba Co.: 3.1 km E Catawba, along Catawba River (35.7021°N, 81.0434°W). 6 Sept. 2007. David G. Cooper et al. NCSM 77310. New county record.

CHRYSEMYS PICTA PICTA **(Eastern Painted Turtle)**. Davidson Co.: 9.0 km SSE center Lexington (35.74689°N, 80.21111°W). 19 June 2012. Bruin DeWald. NCSM photographic voucher BD 12-2. New county record.

Hertford Co.: 6.8 km ESE Como, Chowan River (36.4861°N, 76.9324°W). 16 July 2010. John T. Finnegan and Michael P. Schafale. NCSM photographic voucher JTF 10-1. New county record.

Onslow Co.: 1.1 km S Petersburg (34.9158°N, 77.520878°W). July 2011. Conrad Wernett. NCSM photographic voucher CW 11-1. New county record. Extends range ca. 46 km ESE and 44 km WSW of nearest records in Duplin and Craven counties, respectively (Palmer and Braswell 1995).

CLEMMYS GUTTATA **(Spotted Turtle)**. Vance Co.: 3.6 km S Gillburg (36.2448°N, 78.3626°NW). 16 June 2006. Phil and Alecia LaKernick. NCSM photographic vouchers ALB-11814. New county record.

KINOSTERNON BAURII **(Striped Mud Turtle)**. Bertie Co.: 12.1 km SSW Windsor (35.8959°N, 77.0098°W). 8 August 2002. Alvin L. Braswell, Michael Canada, J. Edward Corey III, and Jean Richter. NCSM 64202. New county record.

Carteret Co. 1.6 km ENE Ocean (34.720410°N, 76.96967°W). 12 July 2010. Jeffrey C. Beane, Brandon Fulton, Jeffrey G. Hall, Natalia L. Smith, and Bryan L. Stuart. NCSM 77280. New county record.

Tyrrell Co.: ca. 3.1 km S.SW Woodley, Scuppernong River State Park along Scuppernong River (35.867734°N, 76.350560°W). 29 April 2011. J. Edward Corey III. NCSM photo vouchers JEC 11-1. New county record and first record for Albemarle-Pamlico Peninsula.

***PSEUDEMYS CONCINNA* (River Cooter)**. Alamance Co.: 3.9 km SW center Burlington (36.0902°N, 79.4677°W). February–March 2011. Ryan W. Kirk. NCSM 79134. New county record.

Madison Co.: 7.1 km WNW Hot Springs, French Broad River (35.933787°N, 82.886506°W). 24 August 2010. Gabrielle J. Graeter, K. Graeter, and Eric Usher. NCSM 77349. New county record. First specimen voucher for Blue Ridge province in North Carolina, and first record for French Broad River drainage in North Carolina. Extends range ca. 95 km NW of nearest record in Polk Co. (Palmer and Braswell 1995), ca. 112 km W of nearest record in Burke Co. (Herman et al. 2003), and ca. 19 km E of nearest records in Sevier Co., Tennessee (Iverson 1992; Scott and Redmond 2008), filling part of range hiatus shown in Conant and Collins (1998).

Northampton Co.: 5.3 km SSW Rich Square (36.231063°N, 77.317519°W). 28 June 2007. Jeffrey G. Hall. NCSM 78691. New county record.

Pasquotank Co.: 1.0 km WSW Weeksville (36.2047°N, 76.1735°W). 3 June 1964. Joseph R. Bailey and Reeve M. Bailey. NCSM 55516. New county record.

Perquimans Co.: ca. 0.5 km N center Hertford, Perquimans River (36.1943°N, 76.4665°W). 2 July 1975. Jesse P. Perry. NCSM 52958–52959. New county records.

Rutherford Co.: 9.3 km ENE Lake Lure (town), Cove Cr. (35.4558°N, 82.10719°W). 5 May 2010. Stephen J. Fraley, W. T. Russ, and N. A. Bowman. NCSM photographic voucher 100505.1sjf. New county record. Extends range ca. 15 km N of nearest record in Polk Co. (Palmer and Braswell 1995).

Vance Co.: 5.8 km NW Middleburg, Kerr Lake State Park along Kerr Reservoir (36.4403°N, 78.3645°W). 2 August 2003. Bryce Fleming and Lori Fleming. NCSM photographic vouchers LF 97-1. New county record.

Wilkes Co.: ca. 6.6 km WSW Wilkesboro, W. Kerr Scott Reservoir (36.12°N, 81.27°W). March 1997. Joseph H. Mickey. NCSM photographic voucher JHM 97-1. New county record. Extends range ca. 75 km WNW of nearest record in Davie Co. (Palmer and Braswell 1995) and fills part of range hiatus shown in Conant and Collins (1998).

***TRACHEMYS SCRIPTA SCRIPTA* (Yellow-bellied Slider)**. Chowan Co.: 3.7 km SW Valhalla (36.1113°N, 76.6861°W). 11 June 1988. Rufus W. Gaul, Jr. and David Carson. NCSM 71830 (7 eggs removed from road-killed female). First specimen vouchers for county. Palmer and Braswell (1995) reported an unvouchered observational record.

SQUAMATA — LIZARDS

***ASPIDOSCELIS SEXLINEATA SEXLINEATA* (Eastern Six-lined Racerunner)**. Granville Co.: 4.7 km NNW Stem, north slope Bowling Mtn. (36.2337°N, 78.7500°W). 12 Sept. 2010. David G. Cooper and Henry Wood. NCSM photographic vouchers DGC 10-1. New county record.

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko)**. Columbus Co.: 1.9 km S Whiteville (34.3206°N, 78.7028°W). 12 July 2010. Gail Reynolds. NCSM photo vouchers KL 10-1. New county record. This introduced species was first vouchered from North Carolina in 2003, from an apparently established population in New Hanover Co. (Beane et al. 2010; Beane and Corey 2010). It is unknown whether this Columbus Co. record represents an established colony or an isolated introduction.

Orange Co.: 5.2 km N center Chapel Hill (35.9605°N, 79.0525°W). 7 August 2011. Jacob Judd and Jessica Hampton Judd. NCSM 78421. New county record. Numerous individuals of different age classes were observed at this locality during 2011 and 2012 (pers. obs.; A. Iyoob, J. Judd, and J. H. Judd, pers. comm.), suggesting a well-established population.

Wake Co.: 0.5 km WSW center Raleigh (35.7781°N, 78.6421°W). 17 November 2009. Michael E. Dunn. NCSM 77274. 1.6 km ESE center Cary (35.7800°N, 78.7661°W). 30 November 2010. Gail Powell et al. NCSM 77728. New county records and second and third specimen vouchers for North Carolina (Beane and Corey 2010). There have been additional reports of this species at the two Wake Co. localities, as well as unsubstantiated reports from other localities in Orange and Wake counties, suggesting established populations. The population at the second Wake Co. locality (1.6 km ESE center Cary) reportedly originated from several escaped captives in the early 1980s, and has apparently persisted for over 30 years (Daniel F. Lockwood, pers. comm.). Over 400 individuals were captured at this site in June and July 2012, during a mark-recapture study (Kevin Durso, pers. comm.).

***PLESTIODON FASCIATUS* (Common Five-lined Skink)**. Davidson Co.: 9.5 km ESE Linwood (35.744639°N, 80.210972°W). 16 April 2011. Bruin DeWald. NCSM photo vouchers BD 11-1. New county record.

***SCELOPORUS UNDULATUS* (Eastern Fence Lizard)**. Davidson Co.: 9.3 km ESE Linwood (35.744887°N, 80.21031°W). 13 March 2012. Bruin DeWald. NCSM photo vouchers BD 12-1.

***SCINCELLA LATERALIS* (Little Brown Skink)**. Stokes Co.: 4.0 km WNW Danbury (36.42535°N, 80.24270°W). 29 April 2012. Jeffrey C. Beane. NCSM photo vouchers JCB 12-529. New county record.

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead)**. Iredell Co.: 1.6 km ESE Mount Mourne (35.540801°N, 80.829140°W). 26 June 2007. Steven J. Price. NCSM 78705. First specimen voucher for county. Beane and Corey (2010) reported a photographic record, and Palmer and Braswell (1995) reported an unvouchered observational record.

***CARPHOPHIS AMOENUS AMOENUS* (Eastern Wormsnake)**. Rockingham Co.: ca. 14.0 km SSW Reidsville, Haw River State Park (36.2505°N, 79.7565°W). 17 March 2010. Jeffrey C. Beane et al. NCSM 77223. New county record.

***CEMOPHORA COCCINEA COPEI* (Northern Scarletsnake)**. Alexander Co.: ca. 8.0 km NE Taylorsville, Rocky Face Mountain (35.972°N, 81.109°W). April 2010. Cade Coone and Michael S. Coone. NCSM 77237. First specimen voucher for county. Beane and Corey (2010) reported a photographic record from the same locality.

***COLUBER CONSTRICTOR CONSTRICTOR* (Northern Black Racer)**. Davidson Co.: 9.3 km ESE Linwood (35.744887°N, 80.21031°W). 25 August 2010. Bruin and Lori DeWald. NCSM photographic vouchers BD 10-1. New county record.

***CROTALUS HORRIDUS* (Timber Rattlesnake)**. Warren Co.: 0.2 km W Manson (36.42164°N, 78.28503°W). 23 November 2010. Charlie Forsythe. NCSM 78461. New county record. Fills portion of gap between northern Coastal Plain populations and a north-central Piedmont population thought to be isolated (Palmer and Braswell 1995, Conant and Collins 1998).

***FARANCIA ABACURA ABACURA* (Eastern Mudsnake)**. Greene Co.: 7.7 km NNW Jason, Button Branch (35.4416°N, 77.8175°W). 26 April 2010. Rufus W. Gaul, Jr. NCSM 77236. New county record.

***LAMPROPELTIS ELAPSOIDES* (Scarlet Kingsnake)**. Camden Co.: 6.9 km NNW South Mills, Dismal Swamp State Park (36.50422°N, 76.35715°W). 18 April 2012. Jane C. Wyche, Signa B. Williams, et al. NCSM photographic voucher JCW 12-1. New county record.

Gates Co.: 6.4 km NE Gatesville (36.44214°N, 76.69991°W). 26 May 2011. Jane C. Wyche. NCSM 78289. New county record.

***LAMPROPELTIS GETULA* (Eastern Kingsnake)**. Chowan Co.: 2.6 km WSW Hancock (35.0909°N, 76.6545°W). 8 June 2009. Elizabeth Hanrahan. NCSM 77220. First specimen voucher for county. Beane and Corey (2010) reported a photographic record from the same locality.

Davidson Co.: 9.3 km E.SE Linwood (35.744887°N, 80.21031°W). 8 September 2010. Bruin and Lori DeWald. NCSM photographic vouchers BD 10-2. New county record.

***MICRURUS FULVIUS* (Harlequin Coralsnake)**. Robeson Co.: ca. 2.7 km WNW center Lumberton (34.6351°N, 79.0331°W). Early August 2009. Kenneth Jones. NCSM 77078. New county record.

***NERODIA TAXISPILOTA* (Brown Watersnake)**. Northampton Co.: 2.1 km S Gaston, Roanoke River (36.48181°N, 77.64429°W). 24 April 2012. Jim Cole. NCSM photographic voucher JC 12-1. New county record.

***OPHEODRYS AESTIVUS* (Rough Greensnake)**. Bertie Co.: 8.7 km SSE Grabtown, Roanoke River National Wildlife Refuge (35.8902°N, 77.0197°W). 5 June 2011. Jeffrey C. Beane, Mark Berman, and John Ellis. NCSM photographic vouchers JCB 11-1017. First photographic voucher for county. Palmer and Braswell (1995) reported an unvouchered observational record.

***RAMPHOTYPHLOPS BRAMINUS* (Brahminy Blindsnake)**. Wake Co.: ca. 6.8 km NW center Raleigh (35.825°N, 78.690°W). Ca. 2 December 1994. Lawrence T. Englert. NCSM 78302. New county record and first record for North Carolina. Thus far, this appears to represent an isolated introduction; no established populations of this widely introduced, parthenogenetic species have been reported in North Carolina.

***REGINA SEPTEMVITTATA* (Queensnake)**. Alamance Co.: 6.1 km SE Alamance, Rock Cr., Cedarock Park (35.995672°N, 79.440916°W). 6 July 2012. Corey T. G. Goldman. NCSM 79771. New county record.

***STORERIA DEKAYI DEKAYI* (Northern Brownsnake)**. Davidson Co.: 9.7 km ESE Linwood (35.74475°N, 80.209806°W). 18 April 2011. Bruin DeWald. NCSM photo vouchers BD 11-2. New county record.

Rutherford Co. 1.9 km ESE Thermal City (35.51303°N, 81.95294°W). 8 June 2012. Jeffrey C. Beane, Robert A. Davis, et al. NCSM 79522. New county record.

***THAMNOPHIS SAURITUS SAURITUS* (Common Ribbonsnake)**. Anson Co.: 5.0 km ENE Ansonville, Pee Dee National Wildlife Refuge, along Pee Dee River (35.10546°N, 80.05385°W). 4 October 2007. W. Jeffrey Humphries. NCSM photographic voucher WJH 07-1. New county record.

Moore Co.: 4.8 km WSW Pinebluff, Horse Cr. (35.0684°N, 79.5161°W). 2 May 2010. L. Todd Pusser, Tiffany A. Arnold, and Zachary S. Barfield. NCSM photographic voucher LTP 10-1. New county record.

Washington Co.: 12.7 km SSW Cherry, Pocosin Lakes National Wildlife Refuge (35.7390°N, 76.4720°W). 3 May 2011. L. Todd Pusser. NCSM photographic voucher LTP 11-1. New county record.

***VIRGINIA VALERIAE VALERIAE* (Eastern Smooth Earthsnake)**. Beaufort Co.: 1.4 km WNW Blounts Creek (35.355700°N, 76.973452°W). 17 April and 20 May 2012. Robby Deans. NCSM photographic vouchers RD 12-1 and RD 12-2. New county records.

Halifax Co.: 4.8 km ESE Halifax, along Roanoke River (36.3023°N, 77.5447°W). 24 March 2012. Stephen P. Hall and Merrill Lynch. NCSM 79358. New county record.

Jones Co.: 3.7 km ESE Trenton (35.0508°N, 77.3155°W). 19 June 2012. David H. Allen. NCSM 80200. New county record.

Tyrrell Co.: 4.2 km SSE Newfoundland (35.91033°N, 76.11211°W). 5 August 2009. Daniel J. Smith. NCSM photographic voucher DJS 09-1. New county record and first record for Albemarle-Pamlico Peninsula.

Acknowledgments.—I sincerely thank all those whose fieldwork resulted in new distributional records. William M. Palmer reviewed the manuscript.

New County Records and an Update for Kansas and Nebraska, USA

Kansas and Nebraska are states found within the midwestern region and the geographical center of the United States. Although both have enjoyed a long history of herpetological exploration, much still needs to be done to verify the existence and distribution of reptiles and amphibians within the region. Here, I report 24 new county records from this region, supported by photo vouchers. Most collections occurred during May 2012. All voucher photographs are deposited in the Herpetology Section of the Natural History Museum of Los Angeles County (LACM). All were verified by Neftali Camacho. These records were determined by examination of the three regional field guides for the area, Collins et al. (2010), Fogell (2010), and Ballinger et al. (2010). The Kansas Herpetofaunal Atlas (Taggart et al. 2013), an online map of county vouchers, was also consulted for updates to the previously cited publications. Most of these records are for turtles, which are underrepresented in museum collections within the region. Geocoordinates were obtained from GoogleEarth/Google Maps WGS84 datum. All observations were made by the author.

KANSAS

TESTUDINES — TURTLES

***CHRYSEMYS PICTA BELLI* (Western Painted Turtle).** Dickinson Co.**:** Abilene, DOR on I-70 (38.942991°N 97.20183°W). 11 May 2011. LACM PC 1575. This is the first vouchered record of this species in Dickinson Co. with complete locality data. Three voucher specimens exist from 1916 (KU 3191, 3192, 157811), with ambiguous locality information. These specimens were verified by Andrew Campbell on 4 June 2012 as from "Dickinson County" with no further information.

Morris Co.: Council Grove Lake (38.705312°N, 96.497518°W). 14 May 2012. LACM PC 1585. New county record.

***GRAPTEMYS PSEUDOGEOGRAPHICA PSEUDOGEOGRAPHICA* (False Map Turtle).** Dickinson Co.: between Soloman and Abilene, Smoky Hill River (38.906017°N, 97.28424°W). 8 May 2012. LACM PC 1577.

Ottawa Co.: Solomon River S of Bennington (39.014585°N, 97.612513°W). 9 May 2012. LACM PC 1580.

Saline Co.: Soloman River, approx. 1 mi. N Salina (38.887556°N, 97.593758°W). 9 May 2012. LACM PC 1579.

***APALONE SPINIFERA* (Spiny Softshell).** McPherson Co.: Marquette, in Smoky Hill River (38.551195°N, 97.833560°W). 11 May 2012. LACM PC 1581.

Saline Co.: Salina, in Smoky Hill River (38.834272°N, 97.585935°W). 9 May 2012. LACM PC 1578.

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider).** Dickinson Co.: Pond at BSA camp S Abilene (38.880057°N, 97.203546°W). 12 May 2012. LACM PC 1584.

Ellsworth Co.: Kanopolis Reservoir, in Smoky Hill River below dam (38.611095°N, 97.952822°W). 12 May 2012. LACM PC 1583.

Morton Co.: Pond in river bottom in Cimarron National Grasslands (37.135831°N, 101.824225°W). 5 May 2012. LACM PC 1576.

Rice Co.: Little River, in Little Arkansas River (38.376818°N, 97.991388°W). 11 May 2012. LACM PC 1582.

NEBRASKA

ANURA — FROGS

***LITHOBATES CATESBEIANUS* (American Bullfrog).** Greeley Co.: Spalding, in city golf course pond (41.680409°N, 98.374483°W). 23 May 2012. LACM PC 1596.

TESTUDINES — TURTLES

***APALONE MUTICA* (Smooth Softshell).** Saline Co.: Solomon River (38.88751°N, 97.593498°W). 8 May 2012. LACM PC 1600.

***CHELYDRA SERPENTINA* (Snapping Turtle).** Boone Co.: SW Petersburg (41.828648°N, 98.091406°W). 23 May 2012. LACM PC 1594.

Fillmore Co.: approx. 2.9 mi. NNE Fairmont (40.676775°N, 97.578675°W). 22 May 2012. LACM PC 1586.

Hamilton Co.: 40.704159°N, 97.997123°W. 22 May 2012. LACM PC 1590.

Nance Co.: 41.342119°N, 97.975041°W. 22 May 2012. LACM PC 1592.

***CHRYSEMYS PICTA BELLI* (Western Painted Turtle).** Boone Co.: SW Petersburg (41.828631°N, 98.091378°W). 23 May 2012. LACM PC 1594.

Clay Co.: Sutton (40.610672°N, 97.866004°W). 22 May 2012. LACM PC 1589.

Fillmore Co.: approx. 2.9 mi. NNE Fairmont (40.676775°N, 97.578675°W). 22 May 2012. LACM PC 1587.

Garfield Co.: Burwell (41.774923°N, 99.095180°W). 23 May 2012. LACM PC 1597.

BRIAN HUBBS
PO Box 26407, Tempe, Arizona 85285, USA
e-mail: tricolorbrian@hotmail.com

Greeley Co.: 41.683766°N, 98.314841°W. 23 May 2012. LACM PC 1595.

Hamilton Co.: 41.073613°N, 97.999864°W. 22 May 2012. LACM PC 1591

***EMYDOIDEA BLANDINGII* (Blanding's Turtle).** Garfield Co.: Burwell (41.774935°N, 99.095105°W). 23 May 2012. LACM PC 1598.

SQUAMATA — SNAKES

***THAMNOPHIS SIRTALIS PARIETALIS* (Red-sided Garter Snake).** McPherson Co.: 41.554029°N, 101.212865°W. 24 May 2012. DOR. LACM PC 1599.

Acknowledgments.—I thank Curtis Schmidt (Sternberg Museum, Fort Hays University, Hays, Kansas), Travis Taggart (Fort Hays University, Hays, Kansas), and Dan Fogell (Southeast Community College, Lincoln, Nebraska) for their confirmation of species identifications, encouragement, and help with the gathering of these new records, and Neftali Camacho (LACM) for verifying all vouchers.

New and Updated Records of Amphibians and Reptiles from Minnesota, USA

In preparation for the publication of the revised edition of "Amphibians and Reptiles in Minnesota" (Moriarty and Hall, pers. comm.), authors accessioned several new or updated records at the Bell Museum of Natural History (JFBM) based on Oldfield and Moriarty (1994) and Gamble and Moriarty (2006). Previously accessioned vouchers documented during or before 1960 were considered outdated. Vouchered records include physical specimens, digital photographs (accession number preceded by "P") and audio recordings (accession number preceded by "AUD"). Of the 36 records included here, 11 were collected by state employees from the Minnesota Department of Natural Resources - Nongame Wildlife Program, and their acquisition was funded in part by a grant from the State Wildlife Grants Program administered by the U.S. Fish and Wildlife Service. Don Shepard verified records. Geocoordinates are based on datum WGS 84. Fieldwork conducted on federal lands with special-use permit number 32550-11009.

CAUDATA — SALAMANDERS

***AMBYSTOMA LATERALE* (Blue-spotted Salamander).** Chisago Co.: Wild River State Park (45.53672°N, 92.73043°W). 08 June 2009. New county record. E. P. Hoaglund, D. McDermott, and C. E. Smith. JFBM P412.

Geographic Distribution of Herpetofauna of Middle Tennessee

Geographic distribution of Tennessee herpetofauna has been well documented by Scott and Redmond (2002), and is regularly updated via online atlas. However, some distribution gaps remain in the Middle Tennessee region. The following records fill some of these gaps. All specimens were collected from a eight-county area in Tennessee to include Hardin, Hickman, Lawrence, Macon, Marshall, Maury, Smith, and Williamson counties. Identification and distribution of species followed Conant and Collins (1998). All specimens represent new county records supported by Scott and Redmond (1996, 2008). GPS datum is WGS 84. Photo vouchers were deposited in the Austin Peay State University's Museum of Zoology (APSUMZ). Nomenclature follows Crother (2012). All specimens were independently verified by A. Floyd Scott (APSU).

CAUDATA — SALAMANDERS

***EURYCEA CIRRIGERA* (Southern Two-Lined Salamander)**. Maury Co.: Mount Pleasant, Creek 200 m downstream from the fall at Stillhouse Hollow Falls (35.470526°N, 87.26777°W). 10 October 2012. Nicole Foster and Cameron Hargrove. APSUMZ 19386.

ANURA — FROGS

***ACRIS CREPITANS* (Eastern Cricket Frog)**. Macon Co.: Red Boiling Springs, near 1727 Jennings Creek Road (36.447708°N, 85.832877°W). 15 October 2012. Nicole Foster and Mary Christensen. APSUMZ 19380.

Maury Co.: Columbia, 70 m N of boat ramp at Chickasaw Trace along the sandy bank beside the Duck River (35.663503°N, 87.093869°W). 13 April 2012. Nicole Foster and Colleen Conway. APSUMZ 19230.

***ANAXYRUS AMERICANUS* (American Toad)**. Williamson Co.: Nolensville, 1039 Britain Lane (35.971178°N, 86.684675°W). 23 May 2012. Nicole Foster and Michele Dillashaw. APSUMZ 19240.

***ANAXYRUS FOWLERI* (Fowler's Toad)**. Maury Co.: Columbia, 3781 Talley Moore Road (35.67919°N, 86.822966°W). 18 May 2012. Nicole Foster and Michele Dillashaw. APSUMZ 19232.

The Persian Gulf is approximately 1000 km long with a depth of approximately 35 m but with depths of more than 100 m in the Strait of Hormoz. The Persian Gulf Islands in Hormoz strait are part of the Zagros formation; of these, Qeshm Island was formed by collision of the Iran and Arabian plates in the Cenozoic (Janakipour 2007; Majnonian et al. 2006; Motamed 1998). The Gulf has been frequently filled and emptied during glacial and interglacial periods in the Quaternary (Mahmoodi 1988). The sandy dunes along the gulf are important habitat for many amphibian and reptile species in this region. To date, there have been no general studies of the lizards of the islands in the Persian Gulf. Here we report on the lizard fauna of one island, Qeshm, based on surveys in the northern and central parts of the island near Deyrestan village.

Materials and Methods.—Qeshm Island is the largest island in the Persian Gulf and is part of Hormozgan Province. The island is located between 27°01' and 26°32'N and 055°16' and 056°27'E (Fig. 1). The island is 135 km long and the widest part, at about 40 km, is located between Laft and Shibderaz, though in most areas it is approximately 11 km wide. The average annual temperature is 25°C, the warmest month of the year is August (with highs of ~46°C), and the coldest month is January (with lows of ~0°C).

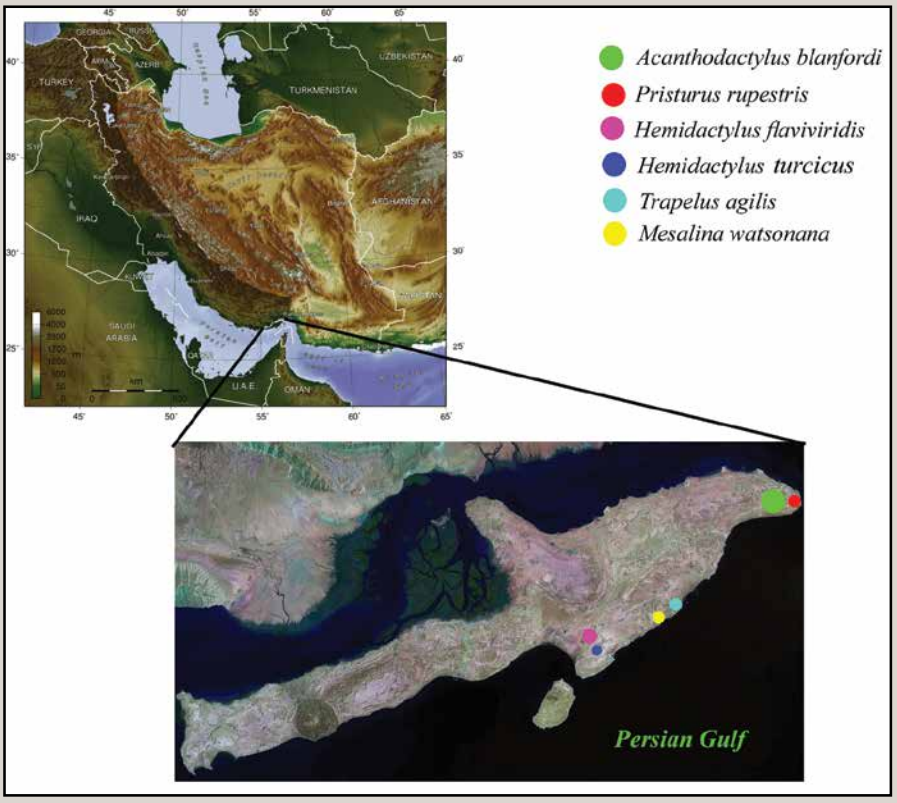

FIG. 1. Map of Iran and the location of Qeshm Island. The location of each species is identified by a different color on the map of the island.

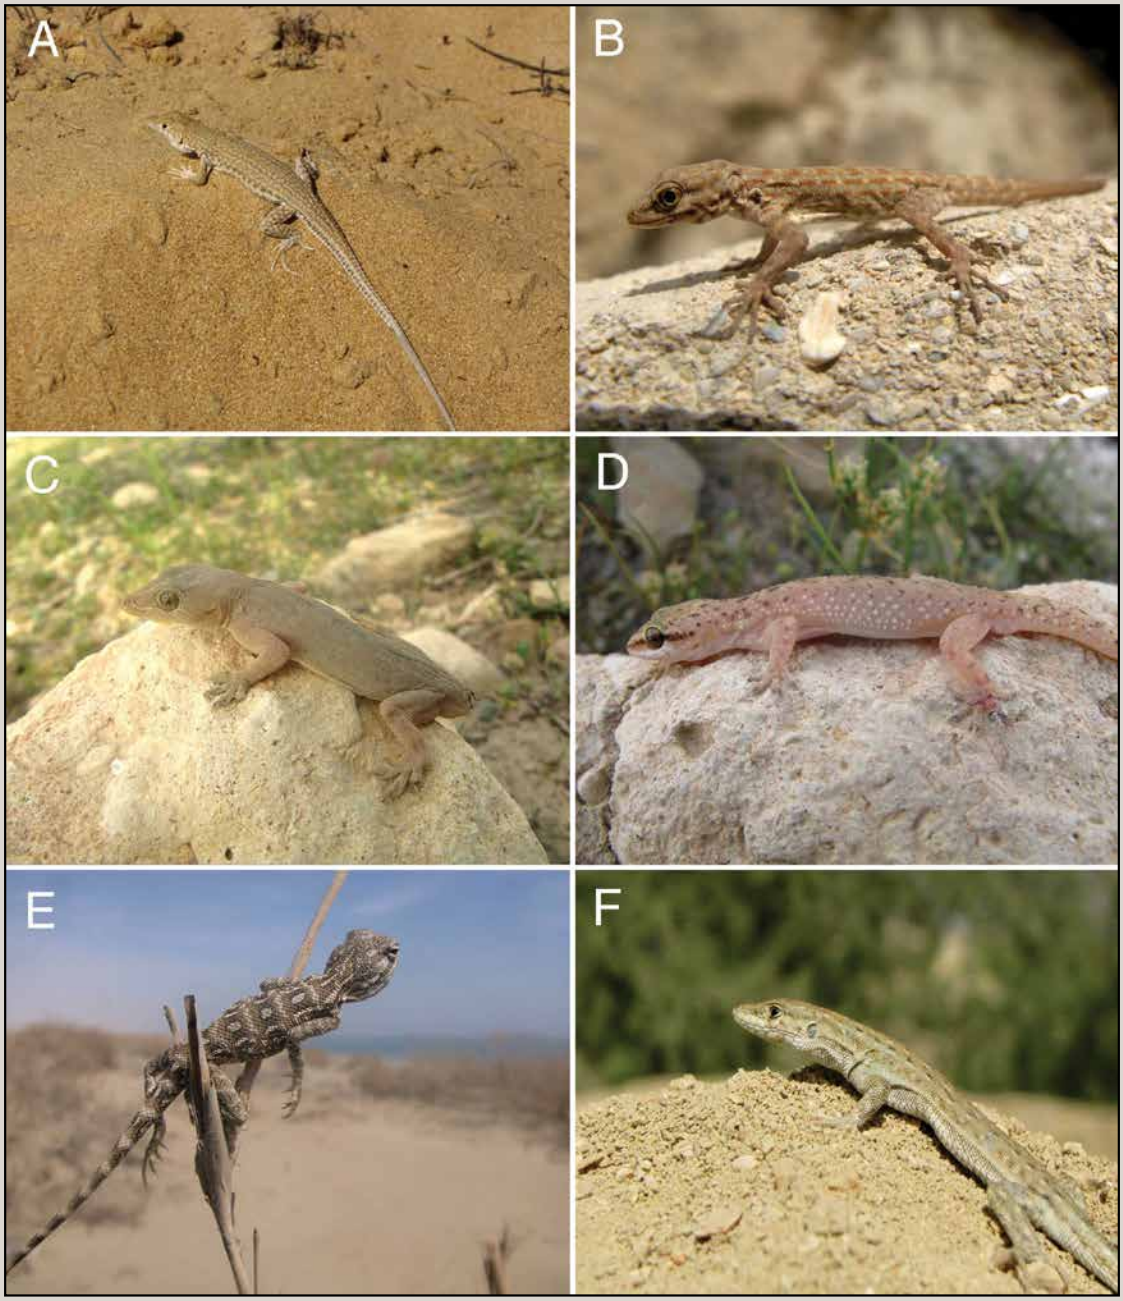
TABLE 1. The species observed and collected from Qeshm Island during our surveys. Specimens are catalogued in the Sabzevar University Herpetological Collection (SUHC).

Museum number	Species	Family
SUHC 844	*Trapelus agilis*	Agamidae
SUHC 855	*Hemidactylus flaviviridis*	Gekkonidae
SUHC 853, 854	*Hemidactylus turcicus*	
SUHC 841, 845, 846, 847	*Pristurus rupestris*	
SUHC 848, 849, 850, 851, 852	*Acanthodactylus blanfordi*	Lacertidae
SUHC 856, 857, 858, 859	*Mesalina watsonana*	

TABLE 2. The complete list of lizards species on Qeshm Island based on supplemental information in the published literature (* = Dakhte et al. 2007).

Species	Family
Trapelus agilis	Agamidae
Hemidactylus flaviviridis	Gekkonidae
Hemidactylus turcicus	
Pristurus rupestris	
*Stenodactylus doriae**	
*Pseudoceramodactylus khobarensis**	
*Tropiocolotes steudneri**	
Acanthodactylus blanfordi	Lacertidae
Mesalina watsonana	
*Scincus mitranus**	Scincidae



Our investigation was carried out in March 2011 on Qeshm Island for three days. Four people surveyed habitats (sand dune, coastal regions, villages) three times each day—morning, afternoon, and early evening. Sampling was by hand, and after obtaining tissue samples for genetic studies, each specimen was fixed according to standard methods in herpetology (Simmons 2002). Localities were recorded by a handheld GPS unit (eTrex Vista 245000 T-E) and digital photos were recorded for each specimen by Canon camera (G7). Voucher specimens are deposited at the Sabzevar University Herpetological Collection (SUHC) and were identified by the published sources for the Iranian herpetofauna (Anderson 1999; Rastegar Pouyani et al. 2007).

Results.—Our surveys identified six lizard species representing three families and five genera on Qeshm Island (Table 1). Based on comparisons to previously published sources on the Iranian herpetofauna, we have added four other lizard species, thus raising the total to 10 species (Table 2).

Discussion.—As mentioned above, the Persian Gulf has been emptied several times in the Quaternary, and during those times, there were land connections between the island and the mainland. The conditions of the island suggest that the herpetofauna is a southern extension of the Arabian fauna (Anderson 1999). Our investigation of the island's herpetofauna indicates that as many as ten lizard species occur on the island (Table 1; Fig. 2; Anderson 1999; Dakhte et al. 2007). Among these, *Pseudoceramodactylus khobarensis* was not recorded from the nearby mainland and Qeshm Island appears to be the northernmost locality for this species (Dakhte et al. 2007). Another species recorded on Qeshm Island, *Scincus mitranus*, probably dispersed from the Arabian Peninsula to the island during the second glacial period before 11,000 years ago (Dakhte et al. 2007). This species has also been reported from Khuzestan, suggesting that it extends into Iranian territory from the Mesopotamian Plain (Fahimi et al. 2009); we expect that future studies may find this species along the northern coastal plains of the Persian Gulf.

Islands are important to understanding phylogeographical patterns and evolutionary divergences. Because the Persian Gulf was a dispersal corridor for the Iranian and Arabian herpetofaunas approximately 20,000–30,000 years ago (Mahmoodi 1988), we suggest that genetic methods on the localized populations in this region will aid our understanding of the history of the island and the biogeography of this region.

Acknowledgments.—We thank Mohammad Dakhte, Mojtaba Ranaei, and Yaser Gholami for help during field surveys and investigations in this region. Our special thanks go to David Blackburn for editing a previous version of this manuscript.

NATURAL HISTORY NOTES

CAUDATA — SALAMANDERS

***AMBYSTOMA MACULATUM* (Spotted Salamander). UNUSUAL EGG ENTRAPMENT.** On 9 March 2012 while surveying ridge-top wetlands in Daniel Boone National Forest (DBNF), Rowan Co., Kentucky, USA, we observed a planorbid snail that had become entrapped in an *Ambystoma maculatum* egg mass (Fig. 1). Planorbid snails are known to feed upon bacteria growing on structures present in water and detritus (Brown and Lydeard 2010. *In* Thorp and Covich [eds.], Ecology and Classification of North American Freshwater Invertebrates, pp. 277–307. Academic Press, London). The individual observed likely became entrapped by either being very close to the jellies as they swelled or attempting to consume bacteria that was present on the egg mass and burrowed in deeply enough to become encased with no mode of escape. To our knowledge, this is the first report of a non-amphibian species becoming entrapped in an egg mass in this portion of DBNF.

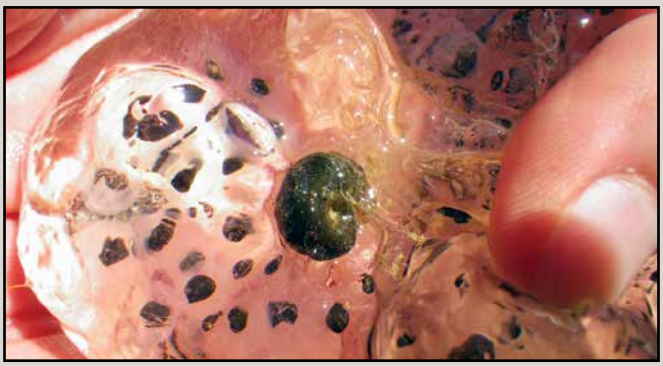

FIG. 1. Planorbid snail entrapped within an *Ambystoma maculatum* egg mass.

DANIEL A. DOUGLAS, Department of Biological Sciences, Eastern Kentucky University, Richmond, Kentucky 40475, USA (e-mail: daniel.douglas@eku.edu); **ANDREA N. DRAYER**, Department of Forestry, University of Kentucky, Lexington, Kentucky 40546, USA.

***BOLITOGLOSSA LIGNICOLOR* (Camron Mushroom-tongue Salamander). PREHENSILITY.** On 15 June 2012, six *Bolitoglossa lignicolor* were observed on a trail system adjacent to the ANAM station (Autoridad Nacional del Ambiente) between 2000–2300 h at the Montuoso Forest Reserve (Herrera Province) in the Azuero Peninsula of Panama (7.73251°N, 80.80033°W; 582 m elev.). When approached, one individual located ca. 1 m off the ground on the leaf of a shrub flipped its body to escape and propelled itself off its perch, catching itself by its tail on a branch about 30 cm below its initial position on the same plant. With the tail encircling the branch, the *B. lignicolor* proceeded to right itself on the branch and returned to its initial perch. To our knowledge there have been no published records where any *Bolitoglossa* has used its tail in any such utility to catch itself or grasp an object following a flipping escape, but this behavior has been observed previously in *B. colonnea* (T. Leenders, pers. comm.; D. B. Wake, pers. comm.). As this behavior has yet to be described, we hereby term the behavior of using the tail in a hook-like fashion to prevent falling and aid in climbing as caudate prehensility.

Similar flipping behavior has been reported in other members of *Bolitoglossa* including *B. colonnea* (Leenders and Watkins-Colwell 2003. Phyllomedusa 2:101–104; pers. obs.), *B. schizodactyla* (pers. obs.), *B. englehardti, B. franklini, B. resplendens,* and *B. subpalmata* (Brodie Jr. 1982. Nat. Geog. Soc. Res. Rep. 14:77–88). These species give a broad representation of the *Bolitoglossa* clade (Pyron and Wiens 2011. Mol. Phylog. Evol. 61:543–583), indicating this behavior may be present within the majority of *Bolitoglossa* species as an ancestral behavior. The mechanics of a similar flipping mechanism has been described in *Chiropterotriton* and *Oedipina*, which are similar bolitoglossine genera (Dodd Jr. and Brodie Jr. 1976. Herpetologica 32:269–290), but such motion has not yet been analyzed in *Bolitoglossa*. All observations of flipping in *Bolitoglossa* occurred while the salamanders were on vegetation or in a laboratory setting, not on solid ground in the rain forest. This behavior has not been observed in laboratory tests of *Bolitoglossa* with snake predators (Ducey et al. 1993. Biotropica 25:344–349), so it is possible that flipping is typically employed as a defense mechanism against large predators that can readily attack *Bolitoglossa* above the ground such as large mammals and birds. Predominantly terrestrial *Bolitoglossa* may not gain the same defensive advantages from flipping that may benefit arboreal salamanders. Although a number of snake predators are known for the genus *Bolitoglossa* (six species listed in Brodie Jr. et al. 1991. Biotropica 23:58–62), other predators are largely unknown or unreported as to corroborate this hypothesis. Further field observations are necessary to determine whether these observations were isolated incidents, or if prehensility occurs frequently within *Bolitoglossa* and perhaps other related species.

We thank D. Laurencio and S. Burton for aid in fieldwork, and D. Wake and T. Leenders for correspondence on this note. Special thanks also to R. Bonett for many insightful comments on this manuscript. The fieldwork during which these observations took place was made possible by NSF grant DEB 0949-359. We complied with all applicable Animal Care guidelines (CMU-IACUC # 10-02) and all federal and international permits are on file and available from K.E.N.

***CRYPTOBRANCHUS ALLEGANIENSIS* (Hellbender). LARVAL DIET.** Little is known about the natural history of *Cryptobranchus alleganiensis* larvae. Only two larval Hellbender diet samples have been published (Smith 1907. Biol. Bull. 13:5–39; Pitt and Nickerson 2006. Herpetol. Rev. 37:69). On 21 Sept 2010, a gilled larva (40 mm SVL, 50 mm TL, 3 g) was collected from beneath a rock during skin diving surveys in Great Smoky Mountains National Park, Tennessee, USA. We flushed the individual's stomach using an Easy Feeder Nipple Tip Syringe (Four Paws Products, Ltd., Hauppauge, New York) filled with river water. The larval *C. alleganiensis* regurgitated an intact *Eurycea* salamander measuring ca. 40 mm TL, which we subsequently preserved in a buffered 10% dilution of concentrated formalin. The Hellbender weighed 2 g following regurgitation.

This is the first report of a first-year *C. alleganiensis* larva consuming vertebrate prey, and also the first indication that *C. alleganiensis* larvae consume other salamander species. Although it has been suspected that larval *C. alleganiensis* feed primarily on aquatic insects (Pitt and Nickerson 2006, *op. cit.*), Smith (1907, *op. cit.*) stated that a second year individual measuring ca. 120 mm TL regurgitated a 60 mm TL conspecific. Hill (2012. Herpetol. Rev. 42:580) indicated that sub-adult *C. alleganiensis* may prey upon salamanders of approximately the same size. The consumption of a large vertebrate prey item relative to body size suggests that young *C. alleganiensis* larvae are able to utilize a wide variety of prey items and may be opportunistic feeders.

This research was conducted under National Park Service Permit (GRSM-2008-SCI-0052) and University of Florida ARC Protocol (#017-08WEC). We thank the National Park Service, The Great Smoky Mountains Institute at Tremont, Philip Colclough, Marcy Souza, and all volunteers for their assistance. Funding was provided by the Cryptobranchid Interest Group Jennifer Elwood Hellbender Conservation Grant, the Reptile and Amphibian Conservation Corps, and the Carlos C. Campbell Memorial Fellowship.

***EURYCEA CIRRIGERA* (Southern Two-Lined Salamander). PARTIAL ALBINO LARVA.** Larvae of *Eurycea cirrigera* are described as having two rows of small, paired, lightly colored dorsolateral spots, and as sometimes having two darkly pigmented dorsolateral lines (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press., Washington, DC. 587 pp.). Although this applies to many larvae of *E. cirrigera* in southern Mississippi, larvae can also vary dramatically in color and pattern from very pale-yellow individuals, to individuals with significant amounts of dark mottling or streaking on their sides (pers. obs.). On 26 July 2012, JYL collected a partial albino larva of *E. cirrigera* (17 mm SVL, 31 mm TL) from a leaf-litter bag deployed at Mill Creek in Forest Co., Mississippi, USA (30.94702°N, 89.24844°W). A total of 48 larvae of *E. cirrigera* were caught in leaf litter traps in Mill Creek during Summer 2012, and 1133 larvae of *E. cirrigera* were caught in traps across the 16 creeks sampled during that summer. This was the only abnormally colored larva collected.

We have identified this individual as a partial albino due to the lack of melanin in the skin, presence of iridophores and xanthophores, and the lack of melanin in the retina (Fig. 1) (Dyrkacz 1981. SSAR Herpetol. Circ. No. 11; Bechtel 1995. Reptile and Amphibian Variants: Colors, Patterns, and Scales. Krieger Publ. Co., Malabar, Florida. 206 pp.). Interestingly, this larva retains the dark, horizontal eye-stripe through the iris that occurs in normally pigmented larvae of this species in this region.

FIG. 1. Partial albino larva of *Eurycea cirrigera* showing retention of dark pigment in the iris of both eyes.

To our knowledge, this is the first record of a partially albino *E. cirrigera* found in Mississippi, if not the first record of albinism in this species elsewhere. However, what makes this *E. cirrigera* intriguing is the retention of dark pigment in the iris, a phenomenon that has been recorded for other species of salamanders. The irises of the albino larvae of *E. bislineata* collected by Bartley (1959. Herpetologica 15[4]:192) retained the eye-stripes typical of that species, and the albino larvae of *Ambystoma opacum* found by Deegan et al. (1998. Herpetol. Rev. 29[4]:229) had regularly pigmented irises. Typically, when albinos are described, the iris lacks melanin and eye-stripes that would have contained melanin in normal individuals appear red (albino *Gyrinophilus porphyriticus*, Hill et al. 2012. Herpetol. Rev. 43[1]:116–117)

We thank G. Thibaudeau, T. Vandeventer, and R. Altig for their insights regarding this larva. Funding was provided by the National Science Foundation Graduate Research Fellowship Program (#0940712), and by U.S. Geological Survey Cooperative Agreement (#G10AC00689). This research was approved by the USM Institute for Animal Care and Use Committee (No. 11061301). After metamorphosis, this specimen will be deposited in the Mississippi Museum of Natural Science in Jackson, Mississippi.

JENNIFER Y. LAMB (e-mail: Jennifer.Lamb@eagles.usm.edu) and **CARL P. QUALLS**, Department of Biological Sciences, University of Southern Mississippi, Hattiesburg, Mississippi 39406, USA.

***HEMIDACTYLUM SCUTATUM* (Four-toed Salamander). REPRODUCTION.** In New Brunswick, Canada, the occurrence of *Hemidactylum scutatum* is based on a small number of specimens observed, but none retained in collections, from sphagnum-shrub (*Kalmia angustifolia*, *Chamaedaphne calyculata*) -rimmed Marven Lake in Fundy National Park (45.571633°N, 65.093460°W). The Fundy National Park (FNP) consists of 206 km^2 of heavily wooded mixed Acadian forest in the Caledonia Highlands along the Bay of Fundy coast (Freedman et al. 2010. *In* McAlpine and Smith [eds.], Assessment of Species Diversity in the Atlantic Maritime Ecozone, pp. 63–70. NRC Press, Ottawa).

The first recorded New Brunswick occurrence of *H. scutatum* is a single presumptive female observed and photographed on 3 May 1983 (Woodley and Rosen 1988. Can. Field-Nat. 102:712; McAlpine 2010. *In* McAlpine and Smith [eds.], *op. cit.*, pp. 613–631). At the time one of us (DFM) confirmed the identification. Marven Lake continues to be the sole location in the province from which the species is known, in spite of extensive searching inside and outside FNP (DFM, unpubl.; M. MacDonald, pers. comm. to DFM). Since 1983, FNP personnel have surveyed Marven Lake on two occasions (1999, 2000) to confirm the persistence of the species. However, beyond presence, no other information regarding the species in New Brunswick has been recorded. In 2012 we obtained a federal Parks Canada permit to collect one whole specimen from FNP and to retain up to three tail-tips for genetic archiving in the New Brunswick Museum (NBM) frozen tissue collection (whole animal: NBM AR 9764; tissue: NBM FTC AR2012.001-002). Here we report on the specimens handled and provide the first reproductive data for the *H. scutatum* in New Brunswick. The province is at the species' northeastern range limit (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. 587 pp.) and at latitude from which there is limited natural history information for *H. scutatum* (Gilhen 1984. Amphibians and Reptiles of Nova Scotia. Nova Scotia Museum, Halifax. 162 pp.).

We visited Marven Lake on 29 June 2012 and during 105 minutes of searching along ca. 15 m of bog shoreline on the northeastern shore of a lake inlet (45.57284°N, 65.09332°W to 45.57310°N, 65.09397°W) located 3 *H. scutatum* egg clutches, two of which were accompanied by females (420 person minutes [pms] of search time; 1 clutch/140 pms). One clutch of 13 eggs was accompanied by a female (71.2 mm TL), and a female (79.9 mm TL) guarded a clutch of 18 eggs. No female was observed with a clutch of 12 eggs. Embryos in all eggs were fully developed and in the 18-egg clutch one embryo was free of the egg envelopes. Egg clutches were located 23–35 mm below the surface of sloping (40–80°) shoreline of *Sphagnum magellanicum*, 126–228 mm from the open water's edge in areas free of shrubs at ca. 256 m elevation.

New Brunswick data for *H. scutatum* presented here agrees with information from adjacent Quebec and Maine. In Quebec clutches of 10–30 eggs predominate (among clutches ranging from 4–114) and most nests (87.4%) are located in pure sphagnum (Desroches et Pouliot 2007. Le Naturaliste Canadien 129:30–33). Likewise, New Brunswick clutches were situated in circumstances similar to those described for Maine by Chalmers (2004. MSc thesis, Univ. Maine, Orono. 109 pp.). There appears to be no previous information concerning hatch dates for *H. scutatum* in Maritime Canada (Gilhen 1984, *op. cit.*), although Chalmers (2004, *op. cit*) reported hatch dates for central coastal Maine from 16 June to 9 July.

This work was conducted under Parks Canada scientific permit FNP-2012-12934. We thank Dan Mazerolle, FNP, for facilitating the issuing of this permit. Michael MacDonald, Stantec Inc., shared information from a 1999 search for *H. scutatum* in FNP. Bruce Bagnell, New Brunswick Museum, kindly identified the *Sphagnum* sp. for us.

***NECTURUS BEYERI* (Gulf Coast Waterdog). DETECTION BY LEAF LITTER BAG.** Leaf litter bags made of plastic mesh and stuffed with leaf litter, are passive traps used to sample salamanders (Pauley et al. 1998. Banisteria 12:32–36; Waldron et al. 2003. Appl. Herpetol. 1:23–36). This method has detected at least 28 species of Plethodontidae. Prior to this note, we only know of one species of salamander outside of this family that has been caught in litter bags (*Necturus alabamensis*) (Graeter et al. 2013. Inventory and Monitoring: Recommended Techniques for Reptiles and Amphibians, with application to the US and Canada. PARC Tech. Rept. Aiken, South Carolina). Herein, we report the detection of *Necturus beyeri* using leaf litter bags.

In November and December 2011, JYL deployed leaf litter bags at 10 creeks within the Pascagoula River Drainage in the DeSoto National Forest, in southern Mississippi, USA. *Necturus beyeri* were caught in litter bags at two of these creeks and identified based on range maps (Guyer 2005. *In* Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 867–868. Univ. California Press, California). Two individuals were caught at Deep Creek (30.93009°N, 88.92031°W), the first on 13 Nov 2011 (20 mm SVL, 37 mm TL), and the second on 16 Dec 2011 (35 mm SVL, 58 mm TL). One individual was caught at Beaver Creek (30.97380°N, 88.93868°W) on 30 Nov 2011 (36 mm SVL, 57 mm TL). No *N. beyeri* were caught from May through July 2012 when the same reaches of Deep and Beaver Creeks were resampled with litter bags. A total of 169 salamanders were caught in bags in Fall 2011, and 1235 salamanders were caught using this method in Summer 2012.

Deep and Beaver creeks are medium-sized creeks. At the tributaries we sampled, these creeks had total drainage areas of 11.8 km^2 and 11.0 km^2 (ArcMap 10.1), and average widths of ca. 2.5 m and 3 m. For both creeks, sampled reaches averaged shallower than 0.5 m. Sand was the dominant substrate, and leaf litter packs, coarse wood, and submerged roots were the most abundant types of available cover. Over the course of litter bag sampling during Fall 2011 and Summer 2012, three species of plethodontids were detected at Deep Creek (*Eurycea cirrigera*, *E. quadridigitata*, *Desmognathus conanti*) and two plethodontids were detected at Beaver Creek (*E. cirrigera*, *E. guttolineata*).

Detecting any organism depends on using an appropriate method in the right place and at the right time. C. Guyer (pers. comm..) found that dip-netting for *N. alabamensis* was a more time-efficient method than was using litter bags. Leaf litter bags may not capture large numbers of *Necturus*, but they have been successful at detecting other cryptic or rare species of salamanders (Waldron et al. 2003, *op. cit.*).

Funding was provided by the National Science Foundation Graduate Research Fellowship Program (#0940712), and by U.S. Geological Survey Cooperative Agreement (#G10AC00689). This research was approved by the USM Institutional Animal Care and Use Committee (No. 11061301).

***SIREN* SP. PREDATION.** On 5 February 2012 at 2027 h, a remote game camera captured a digital image of a Barred Owl (*Strix varia*) perched on stump with a sirenid in its talons (Fig. 1). The game camera was situated along Goodland Creek, a first order stream in the Upper Coastal Plain of Orangeburg Co., South Carolina, USA. Although *Siren intermedia intermedia* (Eastern Lesser Siren) has been captured on the property and is the only

FIG. 1. A Barred Owl (*Strix varia*) landing on a stump with a siren in its talons on 5 Feb 2012 at 2227 h. The species is probably the Lesser Siren (*Siren intermedia*) as several have been captured in the marginal swampy areas of the stream. Wildlife camera set up by Whit Gibbons.

documented sirenid to occur in the creek, *S. lacertina* (Greater Siren) is also found in sluggish intermittent backwaters in the region ("Pen Branch Delta" Luhring and Jennison 2008 J. Fresh. Ecol. 23:445–450) and there are intermittently connected pools on the property. Because the sirenid in the picture appears to be within the size range of a large *S. i. intermedia* or medium *S. lacertina* we are withholding its species-level designation. There are several documented avian predators of "aquatic salamanders" (amphiumids and sirenids) although few cases are specified to the species or even familial level (Luhring 2008. M.S. Thesis, Univ. Georgia, Athens, Georgia). This is the first confirmed observation of a Barred Owl depredating a sirenid.

Funding was provided by the National Science Foundation (Awards DEB-0242874 and DBI-0139572) and the Savannah River Ecology Laboratory under Financial Assistance Award DE-FC09-96SR18-546 between the University of Georgia and the U.S. Department of Energy.

THOMAS M. LUHRING, Savannah River Ecology Laboratory, Drawer E, Aiken, South Carolina 29802, USA. Current address: University of Missouri, Division of Biological Sciences, 105 Tucker Hall, Columbia, Missouri 65211, USA (e-mail: tmlhwb@mail.missouri.edu); **J. WHITFIELD GIBBONS** (e-mail: wgibbons@srel.edu), and **PARKER W. GIBBONS** (e-mail: gibbons@srel.edu), Savannah River Ecology Laboratory, Drawer E, Aiken, South Carolina 29802, USA.

***SIREN LACERTINA* (Greater Siren). PREDATION.** Natural predators of *Siren lacertina* are poorly documented (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington. xvi + 587 pp.). Luhring (2008. MS Thesis, Univ. Georgia, Athens, Georgia) reported two *S. lacertina* presumably, but not conclusively, killed by wading birds; Stevenson et al. (2009. Herpetol. Rev. 40:247–249) reported a predation attempt on an adult *S. lacertina* by a Great Blue Heron (*Ardea herodiea*); and Kilham (1984. Colonial Waterbirds 7:143–145) reported Great Egrets (*Ardea alba*) and White Ibis (*Eudocimus albus*) preying on "large, eel-like salamanders" of uncertain identity.

On 2 Feb 2013 at Viera Wetlands, ca. 8.5 km WSW Pineda, Brevard Co., Florida, USA (28.216°N, 80.762°W; WGS84), we observed an adult American Bittern (*Botaurus lentiginosus*) stalk, catch, subdue, and swallow a subadult (ca. 25–30 cm TL) *S. lacertina* (Fig. 1). The bittern was foraging in thickly vegetated, shallow water at the edge of a wetland, and appeared to be feeling for prey with its feet. After watching the water intently for several minutes, it seized the *S. lacertina* in its bill at 1231 h, but immediately dropped it. After focusing intently on the spot for another 4 min, it grabbed presumably the same siren again and manipulated it with its bill for slightly less than 1 min before swallowing it. The American Bittern is a generalist predator of small aquatic, semiaquatic, and terrestrial vertebrates and invertebrates, including various amphibians (Terres 1982. The Audubon Encyclopedia of North American Birds. Alfred A. Knopf, New York. 1109 pp.), and would be expected to include sirens in its diet. To our knowledge, this represents the first published record of *B. lentiginosus* as a predator of *S. lacertina*.

FIG. 1. An American Bittern, *Botaurus lentiginosus,* preying on the Greater Siren, *Siren lacertina*, Brevard Co., Florida, USA.

ANURA — FROGS

***ANAXYRUS FOWLERI* (Fowler's Toad). INTERSPECIFIC NEST USE.** *Pituophis melanoleucus* (Pinesnake) females in the New Jersey Pine Barrens excavate nests in open canopy, sandy upland areas. Nests, consisting of a tunnel up to 2 m and a hollowed egg chamber, are excavated and not revisited after oviposition (Burger and Zappalorti 1991. J. Herpetol. 25:152–160). The mouth of the tunnel typically collapses within a month of excavation, though the inner tunnel system may stay intact (pers. obs.). Little is known about the biophysical constraints and site selection pressures on *P. melanoleucus* nesting. We study *P. melanoleucus* in the northern extent of its range where it overlaps with several amphibians known to burrow into the sandy soil typical of this region. Specifically, much of the *P. melanoleucus* habitat is shared with the Fowler's Toad (*Anaxyrus fowleri*).

When investigating *P. melanoleucus* nests in the Franklin Parker Preserve, Chatsworth, New Jersey, USA, in July 2011, using a fiber-optic camera, we video captured *A. fowleri* use of an active nest. The toad was located 1 m into the tunnel, not in the egg chamber. At this point, the mouth of the nest was open and there was no sign of additional excavation by the toad. This nest produced four hatchling *P. melanoleucus* that year. Another *A. fowleri* was found in an artificially dug hole near the nest site the same day. The artificial hole was similar in dimensions to

the test holes often dug by female *Pituophis* spp. near true nests, 30 cm deep (Wright 2008. Can. Field Nat. 122:138–141; Burger and Zappalorti 1986. Copeia 1986[1]:116–121). It is unknown if neonate *P. melanoleucus* prey on *A. fowleri*, though the toads are prey to other snakes in the surrounding habitats including Black Racer (*Coluber constrictor*) and Eastern Hognose Snake (*Heterodon platihrinos*). Fowler's Toads have a small annual home range, limited to ca. 75 m diameter (Clark 1974. Am. Midl. Nat. 92:257–274). During *P. melanoleucus* incubation months (July and August), nest tunnels may serve as temperature and humidity refugia for Fowler's Toads. Toad predator avoidance and breeding success are contingent on optimal body temperature and humidity (Preest and Pough 2003. Physiol. Biochem. Zool. 76:229–239). Although the potential effects of toad presence on *P. melanoleucus* egg development are unknown, cooler, humid, and more stable conditions of the subterranean nests may make them important resources for Fowler's Toads (Burger 1989. Behav. Ecol. Sociobiol. 24:201–207).

***COLOSTETHUS INGUINALIS* (Common Rocket Frog). DIET.** *Colostethus inguinalis* is an endemic Colombian species found in the lowlands of northern Choco and the Valley of Magdalena (Grant 2004. Amer. Mus. Novit. 3444:1–24). This diurnal species occurs in rocky areas along the bank of streams in rainforests and mountainous forests. The species is abundant, but populations are decreasing due to deforestation by agricultural and livestock activities, illegal plantations, human establishments, and contamination by fumigation of illegal plantations (Grant and Lynch 2004. IUCN Red List of Threatened Species. Ver. 2012.1 www.iucnredlist.org, 19 March 2013). The food habits and many aspects of its ecology are unknown. Herein we describe the diet of *C. inguinalis* in the dry tropical forest of Colombia in the Natural Reserve of Civil Society Campoalegre (8.48502°N, 76.19520°W; 120 m elev.), municipality Los Cordobas, Department of Cordoba.

We examined 30 stomachs of *C. inguinalis* collected during 0800–1200 h and 1600–1800 h, Feb–Nov 2007 along the banks of streams inside the forest. These samples were collected during the dry season (January–March), first rains (April–June), and heavy rains (September–December). We identified prey to family and genus when possible, measured the length and width of each complete prey item by using a digital caliper (to 0.1 mm). We estimated the volume using the equation for volume of a prolate spheroid.

All frogs collected (N = 30; 15.5–29.5 mm SVL; mean 21.6 ± 2.7) had prey in their stomachs. The diet consisted mainly of arthropods and mollusks (Table 1). Insects (9 orders, 19 families, and 37 morphotypes) and arachnids (especially spiders) were the most important prey. Orthoptera, Coleoptera, and Araneae were the most important volumetrically, however Orthoptera was represented by a single large prey consumed by a single individual. Numerically, the most important prey were ants, *Pheidole* and larval Carabidae and Diptera (Ceratopogonidae). Ants (*Pheidole* and *Solenopsis*) and Staphilinidae had the greatest frequency of occurrence.

TABLE 1. Composition of prey in the diet of *Colostethus inguinalis* from Reserva Campoalegre, Córdoba, Colombia. Volume in mm^3.

We found *C. inguinalis* consumes a large of ants; however, its diet consists of a large number of different prey, which is consistent with other investigations. Volumetrically, the most important prey are somewhat different than those represented in the diet other closely related species.

We are grateful to Fernando Fernández, Vivian Sandoval, Larrys Fontalvo, Yamileth Domínguez, Eduardo Flórez, Orlando Combita, Rodulfo Ospina, Jorge de las Salas, Adriana Tinoco, Ángel Solís, Cesil Solís, and Rudolf H. Scheffrahn for their help in identifying the prey contents. Luis Velazquez provided logistical aid in Reserve Campoalegre. Colciencias and Universidad del Atlántico provided funding for this investigation.

DENDROBATIDAE and *BUFO CONIFERUS*. DEFENSE. Little is known of the taxonomic identity of predators on chemically defended species such as poison frogs of the family Dendrobatidae. Studies of predation on poison frogs have found marks thought to be attributable to ants (Saporito et al. 2007. Copeia 2007:1006–1011; Hegna et al. 2011. Ann. Zool. Fennici 48:29–38), and frogs are occasionally found missing digits, which could also be due to encounters with ants (pers. obs.). Here I describe an interaction of an army ant swarm (*Eciton hamatum*) on three species of poison frogs (*Dendrobates pumilio*, *D. auratus*, and *Phyllobates lugubris*) and on a toad (*Bufo coniferus*) on mainland Panama adjacent to the Bocas del Toro archipelago. Though *E. hamatum* predominantly feed on ants, bees, and wasps (Bartholomew et al. 1988. Physiol. Zool. 61:57–68), differences in their interaction with anuran species provides further evidence for the likelihood of an olfactory signal in the chemical defense of poison frogs.

At 1040 h on 27 Dec 2012 while sampling a polymorphic population of *D. pumilio* from the Aguacate Peninsula an army ant swarm entered the study area. Channels of ants quickly overtook the site and many invertebrates (crickets, katydids, and scorpions) emerged from the leaf litter and escaped. A blue subadult *D. pumilio* became completely surrounded by ants, and remained untouched perched on a leaf. Shortly thereafter three more blue adults and one brown adult were surrounded but also left untouched. Throughout the swarm a small margin (2–3 cm) was maintained between the ants and the frogs. Twenty-four minutes into the ant invasion an adult *D. auratus* perched on a large buttress was similarly approached and avoided as the ants climbed up the tree. Two additional blue and one brown *D. pumilio* were then observed to be surrounded by ants during which one male continued to produce an advertisement call. One hour into the swarm an adult *P. lugubris* and a second *D. auratus* were also surrounded and avoided by ants in a tree buttress, as was a second male *P. lugubris*, which vocalized nearby.

At no point in the column swarm did the ants come into direct contact with any of the three species of poison frogs present in the site; rather the ants maintained about a 2-cm margin from all frogs. In contrast, ants covered a toad (*Bufo coniferous*), which closed its eyes as its body was pressed flat against a tree. Its eyes remained closed until there were gaps in the ant column when its eyes would open, then close again as more ants arrived.

Though this observation unfortunately does not add to our knowledge of specific poison frog predators, it does provide some insight into the possible disparity between results from clay model studies and actual predation. Saporito et al. (2007, *op. cit.*) note that some attack marks on their clay models appeared to be due to the incisors of what they hypothesize could be attributable to *Atta* spp., another group of ants encountered in high densities throughout the tropics. Additionally, the "buffer" distance observed from the frogs could be due to an olfactory component of the alkaloids possessed by these poison frogs which clay models would lack. Poison frog activity during the ant swarm did not appear to be inhibited by the presence of ants. Male vocal advertisements continued for two species during the swarm. At no point did individuals appear threatened by the presence of ants and initiate an escape. These observations further support previous studies mentioning alkaloid olfactory cues in the context of other arthropods, including spiders (*Cupiennius coccineus*; Szelistowski 1985. Biotropica 17[4]:345–346) and other predatory ("bullet") ants (*Paraponera clavata*; Fritz et al. 1981 Biotropica 13:158–159).

***HYLA ARENICOLOR* (Canyon Treefrog). HABITAT USE.** Several species of treefrogs have been documented using tree cavities and avian nest boxes as refugia or hibernacula, including *Hyla chrysoscelis* (Ritke and Babb 1991. Herpetol. Rev. 22:5–8), *H. cinerea* (Redmer and Brandon 2005. *In* M. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 452–454. Univ. California Press, Berkeley, California), and *H. squirrella* (McComb and Noble 1981. Wildl. Soc. Bull. 9:261–267). Treefrogs may use these structures to exploit favorable microclimates or diverse invertebrate food sources. Herein, we report two observations of related behavior in *H. arenicolor*, a treefrog that inhabits isolated mountain canyons in the southwestern USA. Unlike most other treefrogs, *H. arenicolor* is typically found on rock surfaces along stream courses and rarely climbs trees. On 18 June 2012 at 1121 h, we observed three adult *H. arenicolor* inside a Black Phoebe (*Sayornis nigricans*) nest in the Rincon Mountains east of Tucson, Arizona (32.26278°N, 110.62744°W, WGS84; elev. 1068 m; Fig. 1). The cup nest was constructed of mud and plant material and cemented to a vertical rock surface

FIG. 1. Three adult *Hyla arenicolor* in a mud nest constructed by Black Phoebes (*Sayornis nigricans*) in southern Arizona, USA.

ca. 1 m above a bedrock-lined pool, typical of Black Phoebe nests in the desert southwest (Wolf 1997. *In* Poole and Gill [eds.], Birds of North America, No. 268. Acad. Nat. Sci., Philadelphia, Pennsylvania). Similarly, on 21 June 2013 at 1100 h, ERZ observed one *H. arenicolor* in a Black Phoebe nest in another canyon in the Rincon Mountains (32.15668°N, 110.60713°W, WGS84, elev. 1077 m). This nest was attached to the angled underside of a large boulder >0.8 m above the surface of a pool. In both cases, the nests appeared to be intact and undamaged, but there was no evidence that birds had used the nests recently.

Although *H. arenicolor* have lower rates of evaporative water loss than many other anurans (Preest et al. 1992. Herpetologica 48:210–219), they are still at considerable risk of desiccation at midday in June. The bird nests provided shade for the treefrogs, which were >30 mm below the nest opening, likely reducing their risk of dehydration. During summer months, canyon treefrogs are often observed on vertical surfaces of boulders above pools of water, a strategy that presumably reduces rates of predation by vertebrate and invertebrate aquatic predators, including *Thamnophis cyrtopsis* and insects in the family Belostomatidae (Jones 1990. Southwest. Nat. 35:115–122; Swann 2005. Sonoran Herpetol. 18:39–42; Wylie 1981. PhD Dissertation, Arizona State Univ., Tempe, Arizona). Nests may have further reduced risk of predation by concealing treefrogs from potential predators when using these vertical rock surfaces.

***HYLA CHRYSOSCELIS* (Cope's Gray Treefrog). BREEDING ACTIVITY.** Little is known about the biotic and abiotic factors that influence the timing and intensity of reproduction in most anurans. One potentially important but rarely examined factor is lunar phase (Grant et al. 2009. Anim. Behav. 78:349–357). Here, we report observations on the relationship between lunar phase and the intensity of breeding in populations of *Hyla chrysoscelis* in east-central Minnesota, USA.

We observed reproductive activity over six consecutive breeding seasons (28 April to 8 July, 2006–2011) in populations located within 80 km of St. Paul, Minnesota. Teams of 3–4 people used headlamps or handheld lanterns to search for and collect pairs found in amplexus (Fig. 1). Searching occurred between 2200 and 0200 h and was concentrated in areas of ponds with the highest numbers of calling males. Our sampling regime was neither randomized nor systematic in any way; rather, it was guided by the objective of collecting as many pairs as possible each night for use in ongoing behavioral studies of female mate choice; pairs were returned to their collection site within 48 h.

PHOTO COURTESY ROBERT SCHLAUCH

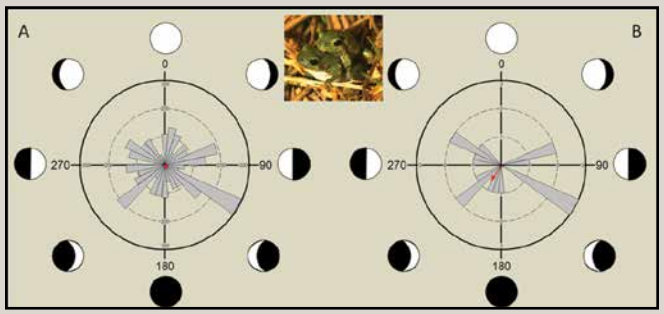

FIG. 1. Lunar cycle and breeding activity in *Hyla chrysoscelis*. Circular histograms showing the distribution, mean vector (μ), and vector strength (r) for A) the number of breeding pairs observed per night over all breeding nights relative to the lunar phase (μ = 141°, r = 0.06); and B) the number of nights on which large breeding events occurred relative to the lunar phase (μ = 213.9°, r = 0.21). Time during the 29.5-day lunar cycle is here expressed as an angle such that 0° and 360° correspond to the full moon and 180° corresponds to the new moon. Inset: Breeding pair of *H. chrysoscelis* in amplexus.

We observed a total of 3293 pairs on a total of 317 "breeding nights" on which at least one pair was observed (range: 1–97 pairs/night; median: 12 pairs/night). The day of the lunar cycle assigned to each breeding night was expressed as an angle and calculated as the days since full moon divided by 29.5 days (0° = 360° = full moon; 180° = new moon). Breeding was statistically more likely to occur closer to the new moon than the full moon when we considered all pairs together (Rao's spacing test: 356.3, p = < 0.01, N = 3293 pairs; Fig. 1A). This trend also held for nights when relatively large breeding events occurred, which we defined as those nights ranking above the 90th percentile within a season in terms of the numbers of pairs collected (median = 70.5 pairs/night, range = 30–97 pairs/night, N = 17 nights). Nights on which these large breeding events occurred were relatively rare around the time of the full moon (Fig. 1B; Rao's spacing test: 168.7, p = < 0.05, N = 17 nights).

These observations suggest lunar phase could be one, albeit weak, factor influencing decisions by some females of *Hyla chrysoscelis* about when to breed. One hypothesis that might explain these data is that breeding, and especially nights when large numbers of females breed, was restricted to darker times during the lunar cycle because of potentially increased risk of predation by visually-oriented predators on nights surrounding a full moon. Other correlates of the lunar cycle (e.g., changes in geomagnetism or gravity), however, might also play some role. Interestingly, our observations contrast with data on several European frogs, for which Grant et al. (2009, *op. cit.*) showed that large breeding events were more likely to occur closer to the full moon. This evidence suggests the lunar cycle might be important in anuran breeding phenology and that there might be patterns of species differences worth investigation.

Research and collecting were conducted with permission from the Minnesota Department of Natural Resources, the Three Rivers Park District, and the University of Minnesota Institutional Animal Care and Use Committee.

***HYPSIBOAS CINERASCENS*. PREDATION.** *Hypsiboas cinerascens* is a small (31–37 mm SVL), common Amazonian treefrog, predominantly arboreal, nocturnal, and frequents the vegetation in riparian and wetland areas (Lima et al. 2006. Guide to the Frogs of Reserva Adolpho Ducke – Central Amazonia. Attéma Design Editorial, Manaus. 168 pp.). Antbirds, Thamnophilidae, are a family of Neotropical passerines that feed predominantly on arthropods, however a substantial proportion of the diet of some species may also consist of small vertebrates, principally frogs and lizards (Poulin et al. 2001. J Trop. Ecol. 17:21–40). On 12 Feb 2013, ACL and I. Thompson found a pair of nest-building Spot-winged Antshrikes (*Pygyptila stellaris*) at the ecotone of degraded primary forest and *varzea* on the left bank of the lower Rio Guama at the Comunidade Menino Jesus, Marituba, Pará

state, Brazil (1.48666°S, 48.31666°W). The birds were loosely associating with a mixed species flock. While under observation the female of the pair was observed carrying a live *H. cinerascens*. The frog was captured within the same tree that was presumed to hold the nest (the female was observed carrying nesting material a few minutes before), which was about 4 m tall and situated in *varzea* forest with a water depth of ca. 50 cm. The *Pygiptila* appeared to experience some difficulty in securing the large prey item and the frog repeatedly grabbed the vegetation surrounding the bird's perch. To subdue the frog the *Pygiptila* was observed to violently bash the frog against its perch on four occasions over the course of two minutes after which point the frog ceased to move. The bird then moved out of sight and we could not confirm that the prey item was consumed. ACL documented the event with a series of digital photographs, reproduced here (WA882353, http://www.wikiaves.com.br/882353&p=1&t=b). *Pygiptila* exhibits a strong preference for foraging for food items extracted from curled dead leaves (Rosenberg 1997. Ornithol. Monogr. 48:673–700), and it is likely that the treefrog was captured in its diurnal hideout under leaves. Although predation of frogs by Thamnophilidae is probably not uncommon we believe this to be the first well-documented incident of such a predation event.

***LEPTODACTYLUS SAVAGEI* (South American Bullfrog). LOCOMOTION AND FORAGING.** In the majority of anurans, individuals in the adult stage move by jumping. Consistently, frogs and toads have several morphological adaptations specific for this type of locomotion (Zug 1972. Copeia 1972:613–624; Zug 1978. Smithson. Contrib. Zool. 276:1–31). Other forms of terrestrial locomotion are also common in anurans including hopping, walking, and burrowing (Wells 2007. The Ecology and Behavior of Amphibians. Univ. Chicago Press, Chicago, Illinois. xi + 1148 pp.). While some species primarily use one form of locomotion, other species combine different forms using specific locomotor behaviors in given contexts. Here we report the observations of a previously undescribed locomotor behavior in *Leptodactylus savagei* (formerly *L. pentadactylus*) performed while foraging.

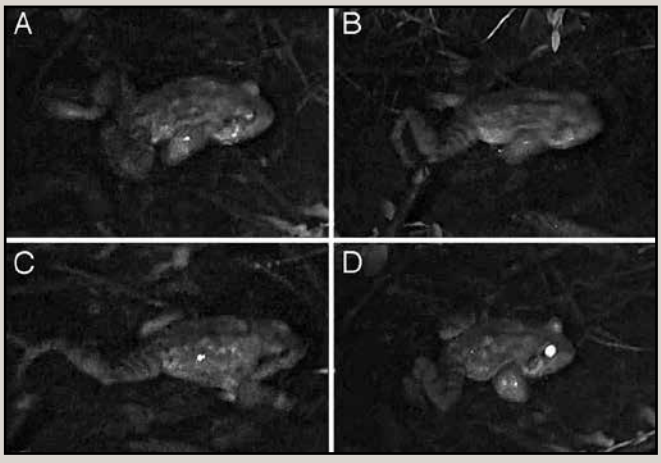

FIG. 1. A) Male *Leptodactylus savagei* with body lowered to the ground prepared to move forward. B) Male lunged forward by force from hind legs. C) The individual *Leptodactylus savagei* stretched with right foreleg in front as the individual crawled forward. D) Male halts crawl and the crouched position is reassumed.

During the evening of 6 August 2012 we observed *L. savagei* actively hunting Túngara Frogs (*Engystomops* [*Physalaemus*] *pustulosus*) at a water channel in Gamboa, Panama (9.11666°N, 79.69833°W). A male *L. savagei* was first observed when it attacked and missed catching a calling male Túngara Frog. After that, the same individual was followed and video recorded while it attacked and consumed three additional Túngara Frogs within 4 m from the first attack. This predator moved by sporadic jumps but once it was closer to a Túngara Frog, within about 100–200 cm, it lowered its body so at least half of it would be submerged under water and began to slowly drag itself towards its prey by staying close to the bottom of the puddle in a movement reminiscent of an army crawl (Fig. 1). When it was within about 30 cm, the *L. savagei* attacked the smaller frog by jumping onto it to catch it by its month. The Túngara Frog was pushed deep into the mouth using the front legs and was rapidly swallowed. After a few seconds of having swallowed the frog, the *L. savagei* scoped for its next victim using the same strategy. We observed this frog-eating predator successfully performing the "jump-army crawl-capture" strategy three consecutive times. In all cases the attacked frogs were calling male Túngara Frogs. Although *L. savagei* is known to be a voracious predator of Túngara Frogs (Ryan et al. 1981. Behav. Ecol. Sociobiol. 8:273–278), hunting strategies have not been described. As in the observations reported here, previous studies have documented *L. savagei* attacking Túngara Frog males aggregated at breeding areas, where the individuals attacked were apparently calling. Eavesdropper predators and parasites that exploit the communication system of Túngara Frogs are known (Tuttle and Ryan 1981. Science 214:677–678; Bernal et al. 2006. Behav. Ecol. 17:709–715), but whether *L. savagei* individuals are also using the mating calls to cue in on this prey needs further investigation.

The army crawl described here is similar to the walking behavior characteristic of some species of frogs (e.g., phyllomedusine hylids). As with walking, crawling involves alternated movement of front and back legs from both sides with little lateral movement of the trunk. It differs, however, in that the body is lowered to the bottom of the puddle and the frog's back legs slide along the ground while the front legs are bent very low. In contrast to jumping, the characteristic locomotor behavior of *L. savagei*, the crawl was performed submerging at least half of the body. The army crawl allows this predator to move closer to its intended prey creating less water displacement by its large body mass and without producing splash sounds associated with jumping. By reaching an appropriate position to seize its prey with minimal disturbance, foraging success is likely improved. Crawling behavior on land has been observed in *Rana esculenta* during feeding (Nauwelaerts and Aerts 2002. J. Zool. 258:183–188), but it is unclear if this sneak attack strategy is deployed by other anurans.

KRISTYN McCOY (e-mail: kristyn.mccoy@ttu.edu) and **XIMENA E. BERNAL** (e-mail: ximena.bernal@ttu.edu), Department of Biological Sciences, Texas Tech University, Lubbock, Texas 79409, USA.

***LIMNONECTES PALAVANENSIS* (Smooth Guardian Frog). OCULAR ANOMALY.** *Limnonectes palavanensis* is a small anuran (to 40 mm SVL) which dwells in the leaf litter of primary

FIG. 1. Front (upper) and dorsolateral (lower) views of an adult *Limnonectes palavanensis* with ocular anomaly found at the Ulu Kimanis Substation, Crocker Range National Park, Sabah, Malaysia.

forest from near sea level to 1502 m elev. (Kueh et al. 2011. Herpetol. Rev. 42[2]:261). The species occurs on Palawan Island of the Philippines, and throughout Borneo (Sabah and Sarawak of Malaysia, Brunei Darussalam, and Kalimantan of Indonesia) (Das 2007. A Pocket Guide: Amphibians and Reptiles of Brunei. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 200 pp.; Inger 2007. Systematics and Zoogeography of Philippine Amphibia. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 370 pp.; Inger and Stuebing 2005. A Field Guide to the Frogs of Borneo, 2nd ed. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 201 pp.).

On 6 Oct 2012 at 2055 h during the Localized Nature Guide Course organized by Borneo Tourism Institute (BTI), an adult male *L. palavanensis* (29 mm SVL) was collected on the forest floor among dead leaves at Crocker Trail (5.4047°N, 116.1104°E; 1049 m elev.), Ulu Kimanis Substation, Crocker Range National Park, Papar District, West Coast Division, Sabah, Bornean Malaysia. The anuran was void of a right eye, while the left eye was present and normal (Fig. 1). Compared to typical *L. palavanensis*, the anuran displayed lighter body hue, but was agile during an indoor *ex-situ* photography session. The anomaly appeared not to affect the overall field of view and did not restrain its visual response and movement. In Dec 2010, Kueh et al. (2011. Herpetol Rev. 42[3]:410) reported ocular anomaly in the microhylid *Chaperina fusca* from highland West Coast, Sabah. Further studies are warranted to determine if such anomaly occurs in other Bornean anuran families and species either with similar or dissimilar effects, the frequency of occurrence of the anomaly in different families and species, and geographical range of the anomaly, to help understand the nature and pattern of ocular anomaly in anurans.

Ocular anomaly in anurans can be caused by physical injuries and selective predation, infections and diseases (fungal infection by *Batrachochytrium dendrobatidis* [*Bd*]), exposure to chemicals and UV radiation, mutation, and developmental errors (Adams et al. 2008. Herpetol. Rev. 39:460–461; Silva and Toledo 2010. Herpetol. Rev. 41:333–334; Streicher et al. 2010. Herpetol. Rev. 41:208–209; Pirani and Moura 2012. Herpetol. Rev. 43:471). However, examination of the anuran showed no body injuries. The anuran was found on a dry trail without any water bodies in the vicinity to corroborate the causal factors of chemical pollution and *Bd* infection.

The anuran was released after photographs and measurements were taken, in accordance to the requirement of the management of Crocker Range National Park under the Sabah Parks. Photographic vouchers are available from the first author. To our knowledge, this is the first observation of ocular anomaly in *L. palavanensis*.

We are grateful to Borneo Tourism Institute (BTI), Sabah Parks, and the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah for support.

***LITHOBATES SYLVATICUS* (Wood Frog). EGG PREDATOR ENTRAPMENT.** On 9 March 2012 while surveying ridge-top wetlands in Daniel Boone National Forest (DBNF), Rowan Co., Kentucky, USA, we observed a *Lithobates clamitans* larva that had become entrapped within an *L. sylvaticus* egg mass. This represents the second observation of an amphibian species entrapped in an egg mass that has occurred in this portion of DBNF (Richter 2012. Herpetol. Rev. 43:459). The *L. clamitans* larva presumably became entrapped while attempting to eat embryos inside the egg mass, as they are known to depredate *L. sylvaticus* eggs (Vasconcelos and Calhoun 2006. Wetlands 26:992–1003). Upon further examination, it was evident that the egg mass had been preyed upon based on the amount of damage observed, however it was undetermined if the entrapped larva or other *Lithobates* larva present in the pond were responsible for the damage.

DANIEL A. DOUGLAS, Department of Biological Sciences, Eastern Kentucky University, Richmond, Kentucky 40475, USA (e-mail: daniel.douglas@eku.edu); **ANDREA N. DRAYER**, Department of Forestry, University of Kentucky, Lexington, Kentucky 40546, USA.

***LITHOBATES SYLVATICUS* (Wood Frog). UNUSUAL MORTALITY.** *Lithobates sylvaticus* is a common species throughout the northern United States and Canada. They are explosive breeders that lay communal egg masses in ephemeral ponds during the early spring. *Lithobates sylvaticus* are often the first amphibian breeders to arrive at these ponds (followed by *Ambystoma jeffersonianum* and *A. maculatum*; J. MacGregor, pers. comm.). On warm, rainy nights, frogs can be seen and heard commuting to

FIG. 1. An array of *Lithobates sylvaticus* egg masses in trees above the pond. Heights above water level ranged from 0 to ca. 1.75 m. The hypothesized laying-freezing-thawing event appears to only have affected those eggs laid early during the breeding season.

FIG. 2. *Lithobates sylvaticus* egg mass ca. 1.8 m above the ground and 1.5 m above water level. The jelly envelops surrounding the eggs were highly desiccated and slightly frozen.

breeding ponds. However, atypical weather patterns can act as false cues for the frogs to begin breeding.

On 31 Jan 2013, several *Lithobates sylvaticus* egg masses were observed in trees overhanging an ephemeral pool (37.519472°N, 084.234128°W) on the border of Rockcastle and Metcalfe counties in eastern Kentucky (Figs. 1, 2). I believe the cause of this phenomenon was an atypically warm and wet night followed by several days (and nights) with temperatures below freezing. The *L. sylvaticus* likely received temperature and humidity stimuli that initiated their breeding behavior. Eggs were then laid in an unfrozen, relatively warm pond. During subsequent weeks, Kentucky (and much of the eastern USA) was hit with an ice storm. Ice deposition on trees must have weighed them down to the point where they entered the water among the frog egg masses. Upon thawing, the trees would have then returned to their position above the ponds pulling the egg masses with them. The scenario presented above appears to be the most likely explanation, but other possibilities surely exist.

This observation emphasizes the important role weather and climate cues play in amphibian life histories. Indeed, as anthropogenic climate change continues to alter weather patterns, occurrences such as this may become more common.

NICHOLAS A. LEVIS, 1906 College Heights Boulevard, Western Kentucky University, Bowling Green, Kentucky 42101, USA; e-mail: nicholas.levis655@topper.wku.edu.

***PSEUDACRIS CRUCIFER* (Spring Peeper). MYIASIS.** Calliphorid flies are known to parasitize North American anurans (Kraus 2007. J. Nat. Hist. 41[29–32]:1863–1874). However, to the best of our knowledge, there have been no published accounts of *Pseudacris crucifer* parasitism by the blowfly *Lucilia sylvarum* (previously *Bufolucilia sylvarum*).

On 24 July 2012, at ca. 0930 h, we observed *P. crucifer* with 32 blowfly eggs of *L. sylvarum* attached to its back. Seventeen eggs were attached just anterior to the sacral hump and lateral of the midline. Another 15 eggs were attached just posterior of the sacral hump, ca. 30 degrees dextral to the anteroposterior axis (Fig. 1).

The specimen was discovered on the ground in southeastern Minnesota, USA, as we collected anurans for a chytridiomycosis survey (44.7245°N, 93.3425°W, 275 m elev.). The frog appeared healthy other than the aforementioned infestation. No lesions, injuries, or signs of disease were noted. Seventeen *P. crucifer*, 4 American Toads (*Anaxyrus americanus*), 22 Gray Treefrogs (*Hyla* sp.), 27 Green Frogs (*Lithobates clamitans*), 2 Northern Leopard Frogs (*Lithobates pipiens*), and 6 Western Chorus Frogs (*Pseudacris triseriata*) were collected

FIG. 1. Spring Peeper (*Pseudacris crucifer*) with blowfly (*Lucilia silvarum*) eggs attached to back.

FIG. 2. Myiasis observed in the Spring Peeper (*Pseudacris crucifer*).

from the same vicinity and inspected for parasites between 24 July and 22 September. No additional instances of blowfly parasitism were observed.

The parasitized *P. crucifer* was held for observation. No efforts to dislodge the eggs were observed and the individual behaved normally until the eggs hatched. After hatching, the maggots quickly penetrated the skin of the host and produced a single lesion just lateral of the dorsal midline and anterior to the sacral hump (Fig. 2). Myiasis and larval development followed the course observed in Wood Frogs (Bolek and Janovy 2004. J. Parasitol. 90[5]:1169–1171) and the specimen was quickly reduced to slurry and bones.

It appears from the number of *L. sylvarum* eggs deposited on the specimen (i.e., 32) that host size and parasitic intensity are uncorrelated variables. Bolek and Janovy (2004, *op. cit.*) observed approximately the same number of *L. sylvarum* eggs on juvenile Wood Frogs in southeastern Wisconsin, USA (i.e., 28–31, N = 2). Although they did not report the mass of the parasitized frogs collected, their photographs and the natural histories of the two species suggest a 2× or greater difference in body mass, with Wood Frogs being substantially larger than *P. crucifer*. American Toads (N = 9) parasitized by *L. sylvarum* in southeastern Wisconsin averaged 8.7 g (Bolek and Coggins 2002. J. Wildl. Dis. 38[3]:598–603), which is ca. twice the mass of a typical *P. crucifer*.

We supplemented the *P. crucifer* carcass with a *L. clamitans* carcass weighing ca. 35 g. The larva reduced both carcasses to bones. Because the eggs of *L. sylvarum* hatch within hours of deposition and the host can be reduced to skeletal remains within 96 h, anuran parasitism by the blowfly *L. sylvarum* is likely to escape notice and may be considerably more common than our observations and published records indicate.

Elevated temperatures resulting from climate change are likely to advance the emergence of anurans and blowflies in the spring, extend their activities in the fall, and increase the cumulative incidence of myiasis in temperate anurans, as anticipated and observed in other species (Goulson et al. 2005. J. Appl. Ecol. 42:795–804). Unfortunately, it may be difficult to document the impacts of climate change on myiasis-induced death rates due to the difficulty of observing myiasis in wild populations and a scarcity of published observations suitable for constructing baseline rates in North American anurans.

We thank University of Minnesota entomologists J. Luhman and P. Tinerella for confirming the identity of the *L. silvarum*.

BRIAN G. WOLFF (e-mail: wolff017@tc.umn.edu) **ERIC WURM**, and **LISA TRACY**, Minnesota State Colleges and Universities, 30 7th St. E., St. Paul, Minnesota 55101, USA.

***RANA DRAYTONII* (California Red-legged Frog). UNUSUAL DEATH.** *Rana draytonii* has been declining in southern California since the late 1960s and is currently listed as Vulnerable by the IUCN and Threatened by the U.S. Fish and Wildlife Service. It has been extirpated in California from San Diego, Orange, Riverside, and San Bernardino counties and only two populations are known for Los Angeles Co.. While conducting surveys on 26 Feb 2013 at the southernmost extant population in the USA in Ventura Co., an adult male *R. draytonii* was discovered dead, entangled in several native blackberry (*Rubus ursinus*) vines just below the surface of the water. The frog's hind right leg was wrapped with six small vines that were cut to free the body. The frog's leg was broken, indicating it struggled to free itself before its demise. The frog was collected (U.S. Fish and Wildlife Recovery Permit TE-045994) and deposited in the Los Angeles County Natural History Museum (LACM 183590). This is contribution 455 of the USGS Amphibian Research and Monitoring Initiative.

FIG. 1. Dead adult male *Rana draytonii* entangled in vines below water surface, Ventura Co., California.

***SCINAX* CF. *ARDUOUS* (Bromeliad Frog). PREDATION.** Composed of 13 species, the *Scinax perpusillus* group is distributed along the Atlantic rainforest between the states of Santa Catarina and Espírito Santo, southeastern Brazil (Frost 2013. Amphibian Species of the World: an Online Reference. Ver. 5.6. Electronic database accessible at http://research.amnh.org/herpetology/amphibia/index.html. American Museum of Natural History, New York). This group is thought to be strictly bromeligenous in having the larval stage associated with water stored in Bromeliaceae (Peixoto 2005. Rev. Universidade Rural 17:75–83). The freshwater crab *Trichodactylus fluviatilis* is widely distributed in the states of Bahia and Rio Grande do Sul (IUCN 2012. www.iucnredlist.org) and is present in freshwater environments, lentic and lotic, where it is known to feed on plant material, eggs, crustaceans,

FIG. 1. Predation of *Scinax* cf. *arduous* by the freshwater crab *Trichodactylus fluviatilis.*

mollusks, and tadpoles. On 6 Oct 2012, at Área de Proteção Ambiental do Mestre Álvaro (20.16722°S, 40.18040°W; 246 m elev.), we observed a male *T. fluviatilis* (2.8 × 3.2 cm carapace) feeding on a *Scinax* cf. *arduous* (2.2 cm SVL) (Fig. 1). The anuran was held by the larger chela (3.6 × 1.6 cm) of the crab. The observation took place on the edge of a stream environment in a secondary patch of Atlantic rainforest. When first observed, the crab was feeding on the anuran, which already had the hind limbs missing. Only photographs were taken, no specimens were collected.

The occurrence of this anuran in the stream environment may be linked to the presence of bromeliads in rock outcrops present in the immediate area of our observation. We cannot confirm the act of predation as the anuran was already being consumed at the beginning of our observation. Because they are associated with different environments, we believe that such interaction between the taxa cited is not frequent, which possibly would not affect the structure of the anuran population in the study area.

We thank H. R. da Silva for frog identification; P. D. F. Júnior and R. B. Ferreira helped with preparation and translation of the manuscript; Prefeitura Municipal de Serra provided the collecting permits (Mat. 32330 – SEMMAN/PMS; SISBIO.: 34371-1).

***SCINAX RUBER*. PREDATION.** Between 2145 and 2210 h on 30 Dec 2009, we observed a *Trachycephalus typhonius* (94 mm SVL) preying on two *Scinax ruber* in the city of Carolina, Maranhão, northeastern Brazil (7.29277°S, 47.49305°W; 168 m elev.). The *T. typhonius* was observed ca. 4 m above ground on a tree. It captured an adult *S. ruber* and in less than 30 min there was a second attack on another adult. Both attacks occurred in savanna (Cerrado) vegetation. When captured, the *T. typhonius* regurgitated the second *S. ruber*, the first was extracted from the stomach. All specimens are deposited in the Herpetological collection of the Pontifícia Universidade Católica de Goiás, Goiânia (*T. typhonius* CEPB9241). These observations confirm that *T. typhonius* is a predator of *S. ruber*, although it is unknown if *S. ruber* is an important dietary item or if they are only sporadically ingested.

TESTUDINES — TURTLES

***APALONE FEROX* (Florida Softshell). DIET.** *Apalone ferox* is thought to be omnivorous, with a strong preference for carnivory. Although the majority of reported prey consists of invertebrates, a wide variety of vertebrate prey has been documented, including fish, turtles, snakes, and birds. Ranid frogs are, to date, the only reported anuran prey (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.).

FIG. 1. *Apalone ferox* feeding upon the lower leg of a still living *Rhinella marina*.

On 12 September 2012 at approximately 0900 h, an adult *A. ferox* was observed in a drainage canal in Homestead, Florida, USA (25.471190°N, 80.468122°W). At the time of observation, the *A. ferox* was in the process of partially consuming a still living *Rhinella marina* (Fig. 1). The turtle proceeded to consume much of the toad's lower right leg. It is unknown whether the *A. ferox* consumed the remainder of the *R. marina*, as the observer left the area before the end of the feeding event.

This documents the first known instance of *A. ferox* preying upon *R. marina*. *R. marina* was introduced to south Florida in 1955 as a result of an accidental release at Miami International Airport (Krakauer 1968. Herpetologica, 24:214–221). It has since expanded its range to include much of south and central Florida (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final Report, Project Agreement 08013, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). The relationship between *R. marina* and native south Florida predators has received little attention. *R. marina* possess large parotoid glands that produce bufotoxins, which can result in cardiac failure if ingested (Toledo and Jared 1995. Comp. Biochem. Phys. 111A:1–29). Mortality associated with ingestion of *R. marina* has been attributed to the decline of certain predatory species, especially within their introduced range (Letnic et al. 2008. Biol. Conserv. 141:1773–1782). However, consumption of *R. marina* resulting in little to no detrimental effect has been documented in several species of vertebrates (Phillips et al. 2003. Conserv. Biol. 17:1738–1747; Calderón-Patrón et al. 2012. Herpetol. Rev. 43:125; Beaty and Beaty 2012. Herpetol. Rev. 43:471). In the case of this observed predation by *A. ferox*, it is possible that by feeding primarily on the lower leg of the *R. marina*, the turtle avoided the high concentration of bufotoxin produced on and near the parotoid glands.

JAMES P. FLAHERTY, Center of Excellence for Field Biology/Department of Biology, Austin Peay State University, Clarksville, Tennessee 37040, USA (e-mail: jflaherty1@my.apsu.edu); **JOSH FRIERS**, Department of Biology, State University of New York at Potsdam, Potsdam, New York 13676, USA.

***CHELYDRA SERPENTINA* (Snapping Turtle). DIET.** *Chelydra serpentina* is known to have a varied diet of both plants and animals, as well as carrion (Ernst and Lovich, 2009. Turtles of the United States and Canada, 2nd ed., Johns Hopkins University

FIG. 1. Snapping Turtle with dewberry stains and remnants on its jaws.

Press, Baltimore, Maryland. 827 pp.). During a survey of the Louisiana Nature Center (heavily damaged by Hurricane Katrina in late August 2005) by the Gulf Coast Herpetological Society on 15 April 2012, a large male *Chelydra serpentina* (CL = ± 33 cm) was observed on the bank of the Farrar Canal feeding on ripe Southern Dewberries (*Rubus trivialis*). When encountered (by IW and SW) the turtle was holding a berry in the front of its mouth, apparently positioning it for swallowing. The turtle's mouth on each side of the berry was stained red, suggesting that the turtle had eaten other berries (Fig. 1). Amy LeGaux, of the Audubon Nature Institute, encountered a Snapping Turtle of similar size eating dewberries along the same canal on 1 April 2013. We believe this is the first report of dewberries in the diet of this species.

***CHRYSEMYS PICTA* (Painted Turtle) and *CHELYDRA SERPENTINA* (Snapping Turtle). COMMENSALISM.** Over a period of several years (late-1980s to 1992) from late spring to early fall, I observed apparent commensalism between *Chrysemys picta* and *Chelydra serpentina* in a pond (area = 0.15 ha) in Williamson Township, Wayne Co., New York, USA (43.2131°N, 77.1771°W; WGS 84). This site was visited weekly, and on approximately two-thirds of all visits, I observed a small *Chrysemys picta* (10 cm carapace length [CL]) always in close proximity (approximately 2 m) to a very large *Chelydra serpentina* (ca. 45–50 CL). During the entire duration of all observations (2–3 per visit, and up to 10 minutes each), the *Chrysemys* would promptly move as necessary to maintain its position behind the *Chelydra*, presumably to avoid a predation attempt. When the *Chelydra* was observed feeding upon frogs and fishes, the *Chrysemys* would occasionally snap at and consume small food scraps that floated behind the *Chelydra*. Whenever I came within view of the *Chelydra*, it would immediately dive into the aquatic vegetation at the bottom of the pond and the *Chrysemys*, which was evidently more focused on the *Chelydra* than its other surroundings, would follow the same flight path after about a two-second latency.

On one occasion, while attempting to capture the *Chelydra* by net, the *Chrysemys* was opportunistically captured instead. The *Chrysemys* was sexed (as a male) and measured, and was clearly in healthy condition, as the soft body parts at the base of its anterior and posterior legs were bulging, and the plastron was slightly convex. The *Chrysemys* was released onsite within 5 minutes of capture. A week later, I returned to the site and the two turtles were again in association as observed during previous visits. This symbiotic relationship continued to the time of my last visit in August 1992. I can find no reference to a commensalistic relationship between these species in the literature. *Chrysemys* is a known prey item of *Chelydra* (Ernst and Lovich 2009. Turtles of the United States and Canada. Smithsonian Institute Press, Washington D.C. 827 pp.), and thus such behavior incurs a potential risk to the *Chrysemys* of which it was evidently aware because it focused upon and always remained posterior to the *Chelydra*. However, in doing so, the *Chrysemys* was less wary of and thus more vulnerable to other potential threats, as evidenced by its capture by me. Nonetheless, this was apparently a long-term and beneficial relationship for the *Chrysemys*, as evidenced by its healthy condition. Due to abundant food sources available to the *Chelydra*, it is highly improbable that the scavenging activities by the *Chrysemys* resulted in food deprivation or any other adverse impacts to the *Chelydra*. Therefore, I believe this is a genuine example of commensalism between these turtles.

JOHN G. HIMES, Florida Fish and Wildlife Conservation Commission, Panama City, Florida 32409, USA; e-mail: John.Himes@MyFWC.com.

***CLEMMYS GUTTATA* (Spotted Turtle). REPRODUCTION.** Little is known regarding the ecology of *Clemmys guttata* on barrier islands (Mitchell and Anderson 1994. Amphibians and Reptiles of Assateague and Chincoteague Islands. Virginia Museum of Natural History, Martinsville. 120 pp.). At 1400 h on 18 March 2004 (air temperature = 9°C) on Assateague Island, Maryland, a pair of Spotted Turtles was observed copulating along the shoreline of a brackish marsh (salinity = 2 ppt; conductivity = 1135 µs/cm; pH = 6.4; water temperature = 15°C) in approximately 15 cm of water. The male (CL = 119.9 mm, PL = 89.5 mm, mass = 150 g) was approximately 3 cm below the surface of the water while the female (CL = 107.7 mm, PL = 97.7 mm, mass = 190 g) was under the male and not immediately visible. The male and female had 13 and nine visible annuli, respectively.

DAVID A. STEEN, Department of Fish and Wildlife Conservation, Virginia Tech, Blacksburg, Virginia 24061, USA; e-mail: davidasteen@gmail.com.

***MACROCHELYS TEMMINCKII* (Alligator Snapping Turtle). UNUSUAL HABITAT AND TRAP SURVIVABILITY.** *Macrochelys temminckii* is the largest freshwater turtle in North America and typically inhabits deep creeks and rivers in southeastern and midwestern states (Ernst and Lovich 2009. Turtles of the United States and Canada. Smithsonian Institute Press, Washington D.C. 827 pp.). Juveniles occasionally occupy and prefer shallow water environments (Allen and Neill 1950. Spec. Publ. Ross Allens's Rept. Inst. 4:1–15; Moore 2006. M.Sc. Thesis, Southeastern Oklahoma State Univ.), but adults are typically not found in these habitats unless they are associated with other deeper creeks/rivers (e.g., oxbow lakes, cypress swamps. Sloan and Taylor 1987. Proc. Annu. Conf. Southeast. Assoc. Fish Wildl. Agencies 41:343–348). Herein, we report on an unusually small, shallow creek and marsh habitat utilized by an adult *M. temminckii*, as well as survivability following neck capture in a Conibear trap.

In the spring 2013, AC was daily tending a nuisance furbearer (i.e., nutria, beaver, raccoon) trap line of four Conibear 330

traps (size: 25 cm × 25 cm). Traps were set in small creek channels, gaps in beaver dams, and paths made by furbearers both upstream and downstream of a moderate-sized farm pond dam in Hale Co., Alabama, USA (32.760833°N, 87.629722°W). The pond (6.2 ha) is fed by two intermittent streams, with a small, first order stream (~1–2 m wide) that exits from the dam. Below the dam, the stream flows into several, successive shallow pools that are surrounded by freshwater marsh vegetation (primarily *Polygonum* species [Smartweed] and *Salix nigra* [Black Willow]). The pools along the stream were formed likely due to the constriction of water flow by a culvert that passes underneath a county road (0.1 km downstream of dam, Hale County Road 28). This creek eventually flows into the Black Warrior River (following ~22.5 river km), a large tributary of the Mobile River system, which is inhabited by *M. temminckii* (Mount 1975. The Reptiles and Amphibians of Alabama. The University of Alabama Press, Tuscaloosa. 270 pp.).

On 26 March 2013 (1500 h), AC found a moderate-sized *M. temminckii* (~11.3 kg) captured in a Conibear trap that was set on the edge of one of the shallow pools. The turtle was still alive even though the trap captured the individual around the neck. Because of the size of the turtle and likely struggle after the turtle was captured, the trap was pulled up from its original location, but was still anchored at another point. Therefore, we were unable to determine which direction the turtle was traveling before it entered the trap. The turtle was carefully removed from the trap and placed downstream of the trap site. To confirm the species that AC observed, WS returned to the site with AC (1630 h) and indeed found the *M. temminckii* in the stream approximately 15 m downstream of the trap site. Thereafter, the individual was removed from the creek and found to be full of vigor, while showing no visible signs of trauma to the head and neck region. The individual was photographed (Florida Museum of Natural History Herpetology Department photographic archive, UF 170047) and then placed downstream of the last trap. On 27 March 2013, WS and AC returned to the site and did not find the *M. temminckii*.

The habitat at the capture site is unique for this species for multiple reasons. First, the area downstream of the dam and around the capture site is not typical habitat for *M. temminckii*; it was a marshy, ephemeral shallow pond setting and more typical habitat for other pond turtle species such as *C. serpentina* and kinosternid turtles. Second, the stream below the dam, between the shallow pools, and downstream of the county road is relatively narrow (1–2 m wide) and while moving through this creek, the *M. temminckii* individual likely occupied most of the channel width. Third, the creek was relatively shallow (10–61 cm deep) and in some sections, the water likely did not completely cover the adult turtle. It is unknown why this individual was in this type of habitat, but it may have been seeking more shallow environments during the spring for thermoregulatory reasons as suggested by Riedle et al. (2006. Southwest. Nat. 51:35–40). Further, it is unknown if the turtle came from upstream (farm pond side) or downstream (small, first order stream) prior to being captured in the trap. For both of these scenarios, the habitat is not typical for the species and the closest "apparently suitable" creek habitat is >15 river km downstream. However, *M. temminkii* will disperse over long distances (Wickham 1922. Proc. Oklahoma Acad. Sci. 2:20–22), which might explain the presence of this individual in this apparently unsuitable habitat.

The Conibear trap is designed to be "triggered" by a target animal and to snap shut and kill the target animal quickly via fracturing of the spinal column or asphyxiation. Thus, Conibear 330 traps effectively kill large beavers, otters, and nutria. However, many non-target species are captured with these body-gripping traps, including larger turtles. AC captured approximately 20 turtles via Conibear trap at this site over six months of trapping (Snapping Turtle, *Chelydra serpentina*; Red-eared Slider, *Trachemys scripta*), but this was the first and only *M. temminckii* captured. Almost all other turtles captured survived because their shells were strong enough to withstand the force of the trap; however, the lone mortality was a *C. serpentina* that was similarly caught by the neck. Further, smaller turtles are not large enough to trigger the trap mechanism, and thus are likely not killed by larger Conibear traps. It is unknown how long the *M. temminckii* individual had been in the trap, but it was <22 h as the trap was checked at ~1730 h the previous day. The survivability of this individual to a Conibear trap neck capture is probably due to the robustness of the skin and musculature of the neck in this species, which is likely associated with both the thrust-bite feeding and defensive behavior and protection during conspecific aggressive encounters.

WILL SELMAN, Rockefeller Wildlife Refuge, Louisiana Department of Wildlife and Fisheries, 5476 Grand Chenier Hwy, Grand Chenier, Louisiana 70643, USA (e-mail: wselman@wlf.la.gov); **AL CHERRY**, Greensboro, Alabama 36744, USA.

***TERRAPENE CAROLINA* (Eastern Box Turtle). MIDWINTER COMBAT and REPRODUCTIVE BEHAVIOR.** At ca. 1400 h on 13 January 2007, 7.9 km NE of Wewahitchka, Gulf Co., Florida, USA (30.16414°N, 85.14253°W; WGS 84), I observed combat between two adult male *Terrapene carolina*. Conditions were sunny, with a light breeze, and an air temperature of ca. 24°C. When first discovered, the two individuals were ca. 30 cm apart. The smaller (15 cm carapace length [CL]) was inverted on its carapace, and presumably had been overturned by the larger individual (20 cm CL). I placed it right-side-up and stepped back 2 m, whereupon the larger turtle almost immediately charged and overturned the smaller one by placing his head under its carapacial margin and then thrusting his head upwards. I picked up the larger individual and placed it back onto the ground, whereupon it walked into a backwater area of the Apalachicola River and immersed itself in ca. 1 m water. I then picked up and moved the smaller individual ca. 60 cm from its original location and placed it on the ground right-side-up, whereupon it walked to the same area and immersed itself in ca. 1 m water as well.

At ca. 0900 h on 12 January 2013, 5.3 km NE Vernon, Washington Co., Florida, USA (30.65860°N, 85.675661°W; WGS 84), I observed copulation by a pair of *Terrapene carolina*. Conditions were partly sunny, with a moderate breeze, and an air temperature of ca. 18°C. The turtles were located in partial sunlight and adjacent to a large hardwood log. After 5 min of observation from 3 m away (during which time the turtles remained in the same position), I left the area without disturbing the turtles further.

Because a female individual was not seen in the vicinity of the two males during the first observation, it is impossible to determine if the combat behavior was territorial or in defense of a mate or other limited resources. However, with the exception of the Florida Peninsula (Dickson 1953. Everglades Nat. Hist. 1:58–62), reproductive behavior has only been reported in *Terrapene carolina* from spring to fall (Ernst and Lovich 2009. Turtles of the United States and Canada, Smithsonian Institute Press, Washington D.C. 827 pp.). Similarly, of the few reports of potential territorial behavior in *Terrapene carolina* (e.g., Stickel.

1989. J. Herpetol. 23:40–44), none have occurred during the winter. Moreover, in the Florida Peninsula, *Terrapene carolina* is less active during the winter (Pilgrim et al. 1997. Chelon. Conserv. Biol. 2:483–488). Thus, territorial or reproductive behavior by this species during the comparatively cooler winters in the Florida Panhandle (where my observations occurred) would appear to be noteworthy. Additional observations are desirable before conclusions can be made on the causes of these behaviors and their overall frequency of occurrence.

I thank Paul Moler for editorial assistance.

JOHN G. HIMES, Florida Fish and Wildlife Conservation Commission, Panama City, Florida 32409, USA; e-mail: John.Himes@MyFWC.com.

CROCODYLIA — CROCODILIANS

***ALLIGATOR MISSISSIPPIENSIS* (American Alligator). REPORT OF A LARGE FIBROSARCOMA IN A WILD ALLIGATOR.** Neoplastic diseases have been documented in reptiles, and a recent retrospective study noted neoplasia is most common in snakes, followed by lizards, chelonians, and crocodilians (Garner et al. 2004. Vet. Clinics N. Am. Exotic Animal Practice 7:653–671); indeed crocodilians have few reported neoplasms (Jacobson 1984. *In* Laboratory Animal Medicine, pp. 449–476. Academic Press, Orlando, Florida). A fibrosarcoma of the oral cavity was reported in a captive Siamese Crocodile (*Crocodylus siamensis*, Janert 1998. J. Zoo Wildl. Med. 29:72–77). Two cases of fibrosarcomas were reported in the coelomic cavity of snakes (presumably captive, due to reported known ages of 8 and 15 years old; Hes et al. 2007. Veterinarni Lekar 3:49–55). Two additional cases of fibrosarcomas in known captive snakes were described previously (Frye 1991. Biomedical and Surgical Aspects of Captive Reptile Husbandry. Vol. II. Krieger Publ. Co. Malabar, Florida. 637 pp.). Other neoplasms have been described in captive crocodilians (Huchzermeyer 2003. Crocodiles. Biology, Husbandry and Diseases. CABI Publ., Wallingford, Oxon, United Kingdom. 337 pp.

Wild crocodilians have been examined for abnormalities and injuries; a thorough study of 1345 wild caught Saltwater Crocodiles (*Crocodylus porosus*) showed only three (0.2%) had "growths." The crocodiles were released after examination, and histology was not available (Webb et al. 1977. Aust. Wildl. Res. 4:311–319). A similar survey of 797 wild caught Freshwater Crocodiles (*C. johnstoni*) noted only six "growths," two appeared to be associated with older injuries and three appeared to be sites of infection; the other was described as a "lump" in the ventral pelvic region (Webb et al. 1983. Aust. Wildl. Res. 10:407–420); without histology this may not have been a neoplasm. A smaller disease surveillance study of 144 wild caught Nile Crocodiles (*C. niloticus*) did not reveal any growths or tumors; the only external lesions were an old bite injury and a recent puncture injury (Leslie et al. 2011. J. S. Afr. Vet. Assoc. 82:155–159). Other studies have focused on endohelminth prevalence and infections in *Alligator mississippiensis* (Scott 1995. Proceedings of the Wildlife, Production, Management and Utilization Conference, Texas A&M Univ., College Station, Texas. 12 pp.) and more recently on West Nile Virus prevalence in free-ranging American Alligators (hereafter, alligators) in Florida (Jacobson et al. 2005. J. Wildl. Dis. 41:107–114) and Louisiana (McNew et al. 2007. Southeast. Nat. 6:737–742).

The state of Louisiana has an alligator management program which includes a regulated harvest of wild alligators (Elsey and Kinler 2004. *In* Crocodiles. Proc. 17th Working Meeting Crocodile Specialist Group, pp. 92–101. IUCN–The World Conservation Union, Gland, Switzerland and Cambridge UK.). Recently we recovered a harvested wild *A. mississippiensis* with an unusually large growth on the left rear foot (Fig. 1).

The male specimen was harvested on 14 September 2011, total carcass length 9 ft., 4 in. (112 in. or 284.5 cm). It was taken on private property in Terrebonne Parish in southeastern coastal Louisiana. The mass measured approximately 30 cm wide × 30 cm long and 18 cm high. The circumference around the equator was 106 cm, and around the upper and lower poles was 83.5 cm. The mass was 10.4 kg; however that includes a bit of the remaining bone after the limb was crudely excised. Upon palpation the mass was quite solid (not cystic or fluctuant); histological evaluation revealed it was a fibrosarcoma and radiological examination showed evidence of erosion of bony structures (Fig. 2). The alligator appeared relatively healthy; although not particularly robust it was also not emaciated; we are unclear if the alligator

FIG. 1. Wild harvested *Alligator mississippiensis* with large fibrosarcoma on left foot.

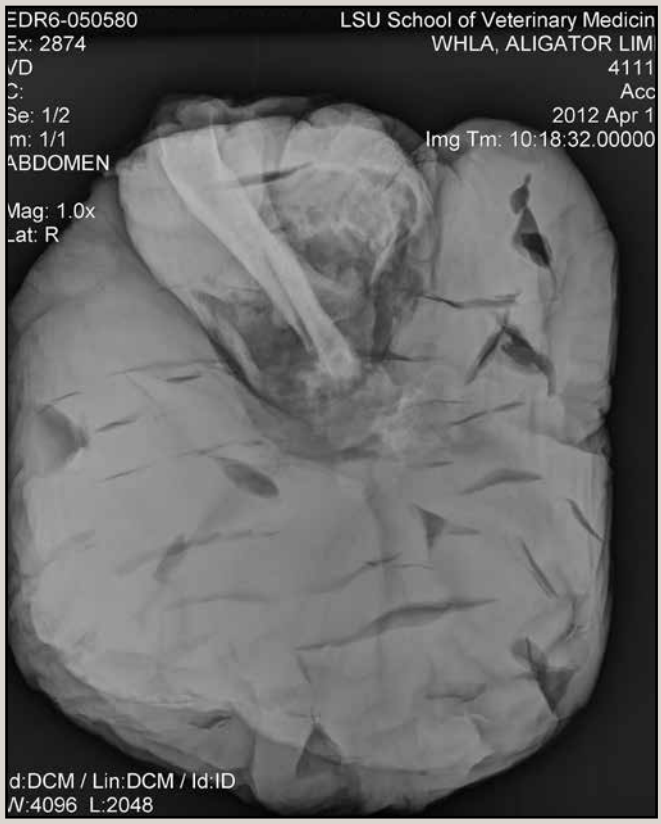

FIG. 2. Radiograph of excised fibrosarcoma from *Alligator mississippiensis*.

could ambulate and it seems likely the volume/bulk of the mass may have interfered with normal streamlined swimming. We surmise the alligator was healthy and feeding, as it was caught on a baited hook as is standard practice in Louisiana. The trapper confirmed he caught all alligators that year by baited hook, and recalls this alligator exhibited normal evasive behavior during the harvest procedure (C. Lovell, Jr., pers. comm.).

To our knowledge this is one of the largest tumors ever reported in a wild crocodilian. It would be of interest to know how long it may have taken for a tumor of this size to develop in a wild alligator. Studies have shown alligators do have a strong capacity to resist infection and their blood has antibacterial (Merchant et al. 2003. Comp. Biochem. Physiol. 136:505–513), amoebacidal (Merchant et al. 2004. J. Parasitol. 90:1480–1483), and antiviral properties (Merchant et al. 2005. Antiviral Res. 66:35–38) but little is known about resistance to neoplasms. A recent study on ocular disease in American Crocodiles (*Crocodylus acutus*) found no association between contaminant accumulation and eye disease, but could not rule out infection or chemical toxicosis as causes of eye lesions (Rainwater et al. 2011. J. Wildl. Dis. 47:415–426). It may be that wild alligators do succumb to malignancies, but after death in the wild carcasses may rapidly deteriorate in ambient heat and humidity, and then are not known to or recovered by researchers. It is possible that environmental stressors such as recent hurricanes in Louisiana followed by drought years may suppress the immune system and predispose some alligators to development of abnormal lesions. Additional research investigating disease mechanisms in valuable crocodilian resources may be warranted.

We thank Rebecca Abshire and staff at D & D (Gueydan, Louisiana) for assistance in collecting tissue samples from the specimen, Todd Conner for reporting the alligator described in this report, and Charles and Chris Lovell for supplying details on harvest of the alligator.

NEVAREZ**, LSU School of Veterinary Medicine, Veterinary Clinical Science, Skip Bertman Dr., Baton Rouge, Louisiana 70803, USA (e-mail: JNevarez@vetmed.lsu.edu).

SQUAMATA – LIZARDS

***AMEIVA POLOPS* (St. Croix Ground Lizard). BEHAVIOR.** We report on burrowing and aggressive behavior in the endangered teiid lizard *Ameiva polops* herein. This species is a relatively small (32–88 mm SVL), active lizard remaining in remnant populations on four small islands <104 m above sea level off the northern and southern coasts of St. Croix, United States Virgin Islands, USA (17.75°N, 64.75°W). Adult males can often be distinguished from females by bluish coloring on the flanks and tail, as well as a deeper red throat patch and the size of the head (Heatwole and Torres 1976. Herpetogeography of Puerto Rico III: 63–111). In its offshore localities, this diurnal species occupies sandy coastal forest with an abundance of dead leaves (Philibosian and Ruibal 1971. Herpetologica. 27:450–454). Individuals retreat overnight in burrows, and previous studies observed that lizard abundance was highest in habitat with loose soil, land crab burrows (*Gecarcinus ruricola*), and ground cover (Heatwole and Torres 1967, *op. cit.;* Meier et al. 1993. Carib. J. Sci. 29:147–152). No reports of burrow construction or defense have been published to our knowledge.

On 22 March 2013, at the end of a trail survey for the species at Buck Island Reef National Monument, USVI (17.7869°N, 64.6192°W), we observed a male *Ameiva polops* between 70 and 75 mm SVL in leaf litter under a small *Pisonia subcordata* shrub. Starting at 1547 h, the individual began rubbing its hind legs briskly on fewer than ten leaves adjacent to the shrub. After 14 minutes, a smaller male (approximately 60 mm SVL) approached the area from the northeast in leaf litter of a Lignum Vitae (*Guaiacum officinale)*. The larger individual continued rubbing his hind legs and tail vigorously on the leaves until the smaller individual was approximately 1.5 m away. The larger individual approached, and both individuals engaged in biting to the head and tails of one another. A large Mangrove Cuckoo (*Coccyzus minor)* came into view but left after the larger lizard chased the smaller lizard up into more dense shrubbery to the north. The animals were not in view for 3 minutes. When the larger male reappeared alone, he returned to his initial position via a circular route 2–4 m from his starting point. He returned to his starting point and continued to intermittently dig in the coarse dirt/sand soil and rub his hind legs on the ground while creating a ramp into the burrow as a pile of course sand accumulated behind him. Eventually he entered the burrow, which we later examined. The entire observation lasted 32 minutes, ending at 1619 h. External burrow dimensions were measured: the entrance was 1.4 mm wide and 1.0 mm high with a 3.2 mm entry ramp under approximately 4 mm leaf litter. We therefore suggest that male *A. polops* construct and/or maintain, as well as defend, burrows to some degree. Further, we believe that the larger male was marking the burrow with femoral pore secretions.

***AMEIVULA ABAETENSIS*. DIET.** *Ameivula abaetensis* is a lizard endemic to the "restinga" habitats from northern Bahia State in Salvador Municipality to south of Sergipe State, Brazil. This species was only recently described and knowledge of its biology and ecology are lacking (Dias and Rocha 2004. J. Herpetol. 38:586–588; Dias and Rocha 2007. Braz. J. Biol. 67:41–46; Dias et al. 2002. Copeia 2002:1070–1077; Dias et al. 2005. J. Herpetol. 15:133–137). Here we present a report on the consumption of a squamate egg by *A. abaetensis*.

A female *Ameivula abaetensis* (SVL = 61.89 mm) was observed eating a soft-shelled elliptical egg (volume = 312.61 mm^3; measuring accuracy of 0.01 mm) at 1300 h on 14 March 2012 at Parque Nacional Serra de Itabaiana, Areia Branca municipally, Sergipe, Brazil (10.747500°S, 37.339444°W; datum WGS84; 201 m elev.). The species that produced the egg was not identified. After feeding on the egg, the specimen was captured by hand (collection permit: 31047–1 IBAMA/RAN), euthanized and deposited in the collection of the Laboratório de Biologia e Ecologia de Vertebrados/Universidade Federal de Sergipe. This is the first documented case of egg predation by *A. abaetensis*. The diet of *A. abaetensis* is known to consist of small arthropods with the presence of various plant matter and fruits (Dias and Rocha 2007, *op. cit.*; Rosa et al. 2012. Bol. Mus. Biol. Mello Leitão [N. Ser.]

29:53–63). Further, *A. abaetensis* is known to prey on juveniles of the lizard *Tropdurus hygomi* (Dias and Rocha 2004. Herpetol. Rev. 35:398–399). Our observation reported here indicates that *A. abaetensis* is a source of mortality in the offspring of small squamates that lack nest attendance behavior by parents.

***AMEIVULA ABAETENSIS*. MATING BEHAVIOR.** *Ameivula abaetensis* is a recently described (Dias et al. 2002. Copeia 2002:928–937) terrestrial and diurnal teiid lizard (Dias and Rocha 2004. J. Herpetol. 38:586–588; Dias and Rocha 2007. Braz. J. Biol. 67:41–46) endemic to coastal sand dune habitats from northern state of Bahia to the southern state of Sergipe, Brazil (Dias et al. 2002. Copeia 4:1070–1077; Tinôco et al. 2010. Herpetol. Bull. 111:19–24). Recent studies on this species include analyses of thermal ecology, activity patterns, habitat use and diet (Couto-Ferreira et al. 2011. J. Threat. Taxa 3:1990–2000; Dias and Rocha 2004. J. Herpetol. 38:586–588; Dias and Rocha 2007. Braz. J. Biol. 67:41–46; Santa-Rosa et al. 2012. Bol. Mus. Biol. Mello Leitão 29:53–63). The only report on the reproductive biology of *A. abaetensis* was provided by Rosário et al. (2011. Herpetol. Rev. 42:428), in which the authors observed the occurrence of oviposition in April. Thus, the aim of this research is present the first report of *in situ* mating behavior of *A. abaetensis*.

On 24 November 2012 at 1137 h, mating behavior of *A. abaetensis* was observed at Restinga de Abaeté, Salvador municipality, State of Bahia (12.914378°S, 38.322402°W; datum WGS84; 31 m elev.). The behavior began with the movement of two individuals within a shrub. After approximately 20 seconds, the subjects moved to the edge of the shrub, the male being guided by the female, where they then mated. At this point, male and female were interconnected by cloacal apposition. The female remained motionless on the sandy soil, while the male was biting her near the pelvic region during the entire copulatory event. Copulation lasted about 30 seconds. At the end of interaction, the two individuals separated and moved to a new shrub, ca. 2 m away. Field observations of behaviors related to reproduction are rarely recorded, even for common species (Mesquita et al. 2012. Herpetol. Bras. 1:41–42). From our observations and those published by Rosário et al. (2011. Herpetol. Rev. 42:428), we believe that *A. abaetensis* begins the reproductive process in intermediate months of the dry season (September to March), with oviposition between the end of this period and the beginning of the rainy season (March to August).

We thank Hilton Japyassú and colleagues from master program in Diversidade Animal/Universidade Federal da Bahia for suggestions and Biocore Tecnologia e Soluções Ambientais Ltda for field support.

DANILO COUTO-FERREIRA, Programa de Pós-Graduação em Diversidade Animal, Instituto de Biologia, Universidade Federal da Bahia, Salvador, Bahia, Brazil and Biocore Tecnologia e Soluções Ambientais Ltda., Salvador, Bahia, Brazil (e-mail: danilocoutoferreira@gmail.com); **EDUARDO JOSÉ DOS REIS DIAS**, Laboratório de Biologia e Ecologia de Vertebrados, Departamento de Biociências, Campus Alberto de Carvalho, Universidade Federal de Sergipe, Itabaiana, Sergipe, Brazil (e-mail: ejrdias@hotmail.com); **IGOR RIOS DO ROSÁRIO**, Programa de Pós-Graduação em Diversidade Animal, Instituto de Biologia, Universidade Federal da Bahia, Salvador, Bahia, Brazil (e-mail: rosario.igor@hotmail.com).

***ASPIDOSCELIS GULARIS* (Spotted Whiptail). PREDATION.** The predation of vertebrates, including lizards, by spiders has been well documented (Ervin et al. 2007. Herpetol. Rev. 38:468; Filipiak and Lewis 2012. Herpetol. Rev. 43:486). Such predation can occur via active foraging, ambush, or the use of webs (Hamilton 2012. Herpetol. Rev. 42:603; Lanschi and Barbosa 2012. Herpetol. Rev. 43:134; Lazcano et al. 2012. Herpetol. Rev. 43:138). Spiders of the genus *Latrodectus* are known to prey on lizards, ensnaring them with self-constructed webs (Lane 2012. Herpetol. Rev. 43:339; Painter and Kamees 2010. Herpetol. Rev. 41:227). To our knowledge this is the first account of predation on *Aspidoscelis gularis* by a Black Widow (*L. mactans*).

On 1 November 2012, at ca. 1100 h, a juvenile *A. gularis* (approximate SVL = 30 mm) was found dead, trapped in spider web occupied by a *L. mactans,* in a cistern near a house (Fig. 1), at Municipality of Chihuahua, Chihuahua, Mexico (28.668856°N, 105.942033°W, datum WGS84; elev. = 1376 m).

Fig. 1. *Aspidoscelis gularis* (juvenile) trapped in a Black Widow Spider web before consumption, in Chihuahua, Chihuahua, México.

***ASPIDOSCELIS NEOMEXICANA* (New Mexico Whiptail) × *ASPIDOSCELIS SEXLINEATA VIRIDIS* (Prairie Racerunner). DURATION OF HYBRIDIZATION.** *Aspidoscelis neomexicana* is a hybrid-derived parthenogenetic species (Cole et al. 1988. Am. Mus. Novitat. 2905:1–38; Parker and Selander 1984. Herpetologica 40:245–252) that reproduces asexually through development

of unreduced diploid eggs. Sexual reproduction in the species occurs only when its eggs are fertilized by sperm from a male of a gonochoristic species such as *A. sexlineata* (Manning et al. 2005. Am. Mus. Novitat. 3492:1–56; Walker et al. 1990. Am. Midl. Nat. 123:404–408) resulting in sterile triploid hybrid males and mostly sterile triploid females. However, it is conceivable that a rare fertile female could become the founder of a new allotriploid parthenogenetic species as has occurred repeatedly through hybridization in the genus *Aspidoscelis* (see Reeder et al. 2002. Am. Mus. Novitat. 3365:1–61).

We used phenotypic attributes to confirm the identity of a hybrid of *A. neomexicana* × *A. sexlineata viridis* in order to establish that hybridization between these species has occurred over a period of >30 years in the vicinity of Conchas Lake and the Canadian River, San Miguel Co., New Mexico, USA. This female (originally catalogued as University of Arkansas Department of Zoology 8578 and recently re-catalogued as Arkansas State University Museum of Zoology 32422) was collected by one of us (JEC) at 1145 h on 9 August 2009 at Conchas Lake in the South Recreation Area (35.377222°N, 104.1094444°W, datum

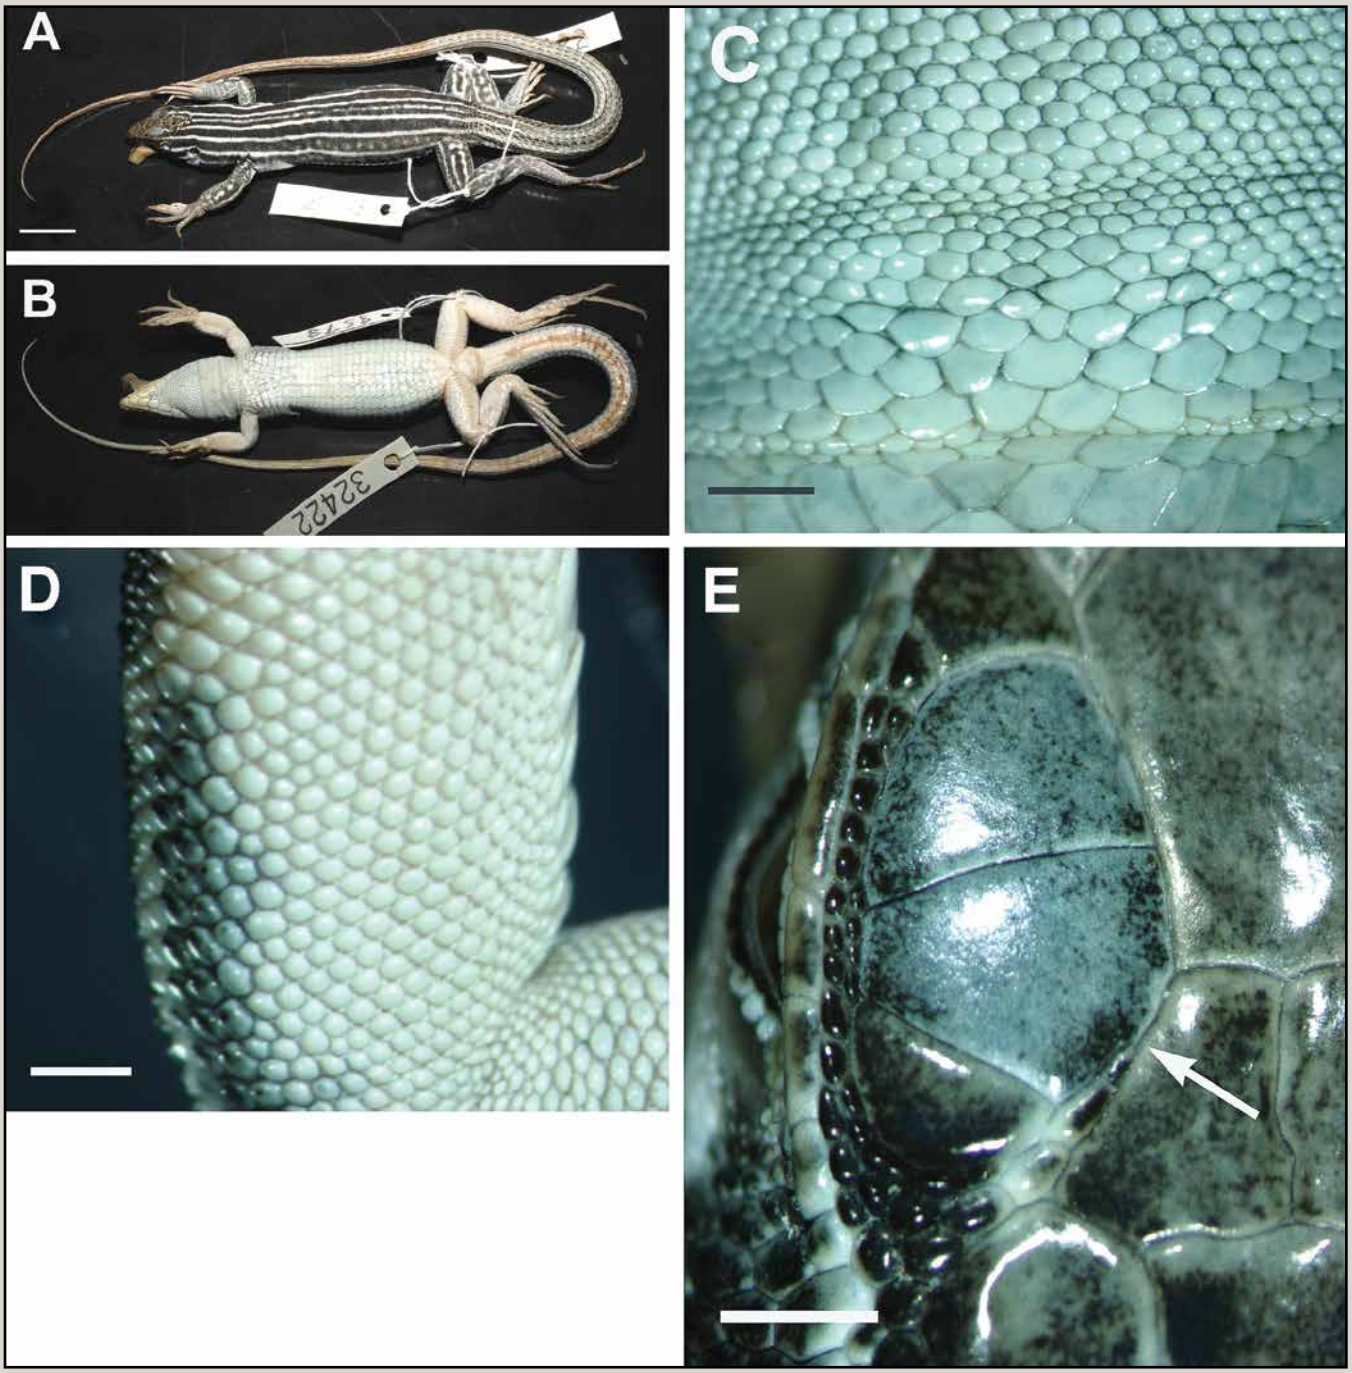

FIG. 1. Color pattern and morphological characteristics of a hybrid female specimen of *Aspidoscelis neomexicana* × *A. sexlineata viridis* from Conchas Lake, San Miguel Co., New Mexico. A) Dorsal coloration and pattern of ASUMZ 32423; line = 10 mm for A and B. B) Ventral coloration of ASUMZ 32422. C) Moderately enlarged mesoptychial scales of ASUMZ 32432; line = 1 mm. D) Slightly enlarged postantebrachial scales of ASUMZ 32422; line = 1 mm. E) Incomplete circumorbital scale series (see arrow) in ASUMZ 32423; line = 1 mm.

WGS84; ~1272 m elev.). In this area, one of three near Conchas Lake where hybrids between these species have been collected (Manning, *op. cit.*), the guild of whiptail lizards includes *A. exsanguis* (triploid parthenogen, rare), *A neomexicana* (diploid parthemogen, abundant), *A. sexlineata viridis* (gonochoristic, moderately abundant), and *A. tesselata* pattern classes C and D (diploid parthenogens, moderately abundant). Prior to preservation, ASUMZ 32422 had a SVL of 71 mm, tail length of 244 mm, and body mass of 9.2 g. It could not be identified to *A. sexlineata viridis* because of the presence of spots (i.e., rounded pale areas) in the dark fields between the stripes, parts of primary stripes with uneven margins, and distinct vertebral stripe with interruptions. *Aspidoscelis sexlineata viridis* is characterized by straight-margined stripes and lack of spots throughout ontogeny (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America, 3rd ed. Houghton Mifflin Co., New York, New York. 616 pp.; Perez-Ramos et al. 2010. Southwest. Nat. 55:420–426; Trauth 1992. Texas J. Sci. 44:437–443). Although the specimen resembles *A. neomexicana* more closely than *A. sexlineata viridis*, characters indicating its hybrid origin are these intermediate aspects of color pattern (Fig. 1A–B): paired lateral and dorsolateral stripes relatively straight-margined only posterior to level of the forelimbs, paired paravertebral stripes relatively straight-margined anterior to forelimbs and unevenly margined posteriorly, vertebral stripe single and relatively straight-margined anteriorly and with numerous interruptions posterior to forelimbs, strongly contrasting pale stripes and dark fields to produce an ornate effect, large round spots in the fields superior to the lateral stripes, and off-white rather than gray-blue venter. Observations for three characters of scutellation are also consistent with the hypothesis for a hybrid origin for ASUMZ 32422 (comparison with *A. neomexicana* in paren): moderately enlarged mesoptychial scales bordering the gular fold (Fig. 1C, rather than small); very slightly enlarged postantebrachial scales on posterior aspect of forelimbs (Fig. 1D, rather than granular), and incomplete circumorbital scale series between supraocular and median head scales (Fig. 1E, rather than extending anteriorly past the second supraocular sutures or with complete series).

The specimen described herein establishes that production of viable, if infertile, hybrids of *A. neomexicana* × *A. sexlineata viridis* has been ongoing in the vicinity of Conchas Lake for more than 30 years. The first of these was collected by B. E. Leuck and companions on the north side of the Canadian River/Conchas Lake in 1978 (Manning et al., *op. cit.*) followed by collection of other hybrids on the south side of the lake/river between 1988 and 2009 (Manning et al., *op. cit.*; Walker et al., *op. cit.*; this study). The general area from which ASUMZ 32422 was collected on the south side of Conchas Lake has been the source of more than a dozen hybrids to date. An internal examination of the present hybrid by one of us (SET) revealed the following: right oviduct elongated and thin, undeveloped; right gonad translucent, around 3 mm in length, and only slightly larger in width than its associated ligament, no evidence of ova; left oviduct elongated and slightly developed; left gonad translucent and minute (around 2 mm in length), and only slightly larger in width than its associated ligament; no evidence of ova. Both abdominal fat bodies were yellow and greatly enlarged. We infer that the individual was sterile.

Specimens from San Miguel Co. referenced in this study were collected under authority of permit number 1850 issued to JEC by the New Mexico Department of Game and Fish, and in cooperation with the U.S. Army Corps of Engineers.

JAMES M. WALKER, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701, USA (e-mail: jmwalker@uark.edu); **JAMES E. CORDES**, Division of Sciences and Mathematics, Louisiana State University Eunice, Eunice, Louisiana 70535, USA (e-mail: jcordes@lsue.edu); **STANLEY E. TRAUTH**, Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA (e-mail: strauth@astate.edu); **GLENN J. MANNING**, School of Mathematical and Natural Sciences, University of Arkansas-Monticello, Monticello, Arkansas 71656, USA (e-mail: manning@uamont.edu).

***ASPIDOSCELIS TIGRIS* (Tiger Whiptail). DIET.** On 22 April 2007 at 1410 h in Lower Colorado River Valley subdivision Sonoran Desert (Brown 1994. Biotic Communities: Southwestern United States and Northwestern Mexico. Univ. of Utah Press, Salt Lake City, Utah. 342 pp.), just north of the Mexican border south of Yuma, Yuma Co., Arizona, USA (32.420405°N, 111.562379°W; 57 m elev., T_A 26°C), we observed an adult *Aspidoscelis tigris* (98 mm SVL, 209 g) carrying a dead juvenile *Dipsosaurus dorsalis* (Desert Iguana, 56 mm SVL, 4.1 g) in its jaws (photo voucher UAZ 57461-PSV). The head of the desert iguana was badly crushed. The whiptail carried the desert iguana by the head to a Creosote Bush (*Larrea tridentata*) ca. 10 m distant. Once in cover it stopped, repeatedly dropped and picked up the prey, biting down on its head. Within a few minutes the *Aspidoscelis* abandoned its prey, likely disturbed by our presence.

We believe this is the first report of predation of *D. dorsalis* by *A. tigris*. Invertebrates compose the bulk of *A. tigris* prey (Aspland 1964. Herpetologica 20:91–94; Best and Gennaro 1985. Great Basin Nat. 45:527–534; Scudday and Dixon 1973. Southwest. Nat. 18:279–289; Vitt and Ohmart 1977. Herpetologica 33:223–234) and prey varies seasonally (Vitt and Ohmart, *op. cit*). Vitt and Ohmart (*op. cit.*) noted lizard parts in the stomach of one of 82 *A. tigris* examined, and Best and Gennaro (*op. cit.*) found two occurrences of lizard prey in 174 stomachs; species of prey lizards were not reported. It is likely that lizards and perhaps other small vertebrates comprise a small portion of *A. tigris* diet seasonally, perhaps more so in the spring and late summer when young of many lizards are most abundant.

RANDALL D. BABB, Arizona Game and Fish Department, 7200 E. University Drive, Mesa, Arizona 85207, USA (e-mail: rbabb@azgfd.gov); **THOMAS C. BRENNAN**, 8445 E. Natal Circle, Mesa, Arizona 85209, USA (e-mail: t_c_brennan@yahoo.com).

***COLEONYX VARIEGATUS* (Western Banded Gecko) and *RENA HUMILIS* (Western Threadsnake). ATTEMPTED PREDATION.** On 8 July 2008, 2045 h we encountered a small, ca. 127 mm TL *Rena humilis* surface active on the edge of a wash near Queen Valley, Pinal Co., Arizona, USA (33.301018°N, 111.314240°W; 611 m elev.). While we were watching the snake, a ca. 63 mm SVL *Coleonyx variegatus* attempted to prey on it. When the gecko first encountered the snake, it cocked its head to one side then rushed forward a few centimeters and grabbed the snake, which thrashed wildly. The gecko shook it a couple of times, then released it. We do not know if the gecko decided the snake was too large, or if it was simply disrupted by our presence, but we suspect the latter as the gecko fled after dropping the snake.

This is the first report of *C. variegatus* as a potential predator of *R. humilis*. *Coleonyx variegatus* is primarily a predator of small invertebrates (Parker and Pianka 1974. Copeia 1974:528–531), and vertebrate prey is virtually unknown. Though Parker and Pianka (*op. cit.*) documented the remains of four lizards or lizard skin in the stomachs of 185 *C. variegatus* examined, they

did not elaborate as to whether those were ingested shed skin or actual prey items. Though this predation attempt was unsuccessful, it is not unlikely that small vertebrates such as hatchling lizards (e.g., *Uta, Xantusia*) and small snakes (e.g., *Rena, Tantilla, Sonora*) may occasionally fall prey to large *C. variegatus*.

RANDALL D. BABB, Arizona Game and Fish Department, 7200 E. University Drive, Mesa, Arizona 85207, USA (e-mail: rbabb@azgfd.gov); **THOMAS C. BRENNAN**, 8445 E. Natal Circle, Mesa, Arizona 85209, USA (e-mail: t_c_brennan@yahoo.com).

***DIPLOGLOSSUS MONOTROPIS* (Costa Rican Rainbow Striped Galliwasp). PREDATION.** *Diploglossus monotropis* occurs in tropical rainforest from Nicaragua to Colombia and Ecuador (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 994 pp). Information regarding the natural history of this anguid is scarce, including its predators, mainly due to its secretive and nocturnal behavior (Solórzano 2001. Fauna. 2:8–12).

On 26 February 2011 at 1200 h, while conducting herpetofaunal surveys in Veragua Rainforest Adventure Park, Limón Province, Costa Rica (9.926361°N, 83.19095°W, datum WGS 84; 200 m elev.), we observed a Sunbittern (*Eurypyga helias*) standing over a stone at the edge of a river exhibiting feeding behavior. Upon arriving at the site for inspection, a carcass of a *D. monotropis* was found on the same stone where the Sunbittern had been perched. The carcass retained only the back and ribs of the reptile; all the organs were consumed. However, the carcass was relatively fresh (Fig. 1). It is known that this aquatic-foraging bird is capable of feeding on lizards such as *Anolis oxylopus* and *Ameiva festiva* (Lyon and Fogden 1989. Auk 106:503–507). The behavior of the Sunbittern suggests it was original predator of the lizard, or was at least feeding on the carrion, and to our knowledge this would be the first record of predation on a *D. monotropis* (or for the genus *Diploglossus*) by an avian predator. Further, this is the largest lizard species reported for the diet of the Sunbittern to date.

FIG. 1. A) Carcass of *Diploglossus monotropis* (dorsal view). B) Carcass of *D. monotropis* (ventral view).

We thank to Veragua Rainforest and Adventure Park for providing research facilities and to Alejandro Solórzano for suggestions on this note.

***HEMIDACTYLUS FRENATUS* (Common House Gecko). PREDATION.** *Hemidactylus frenatus*, a species native to the Old World tropics (Leenders 2001. A Guide to Amphibians and Reptiles of Costa Rica. Zona Tropical. Miami, Florida. 305 pp.), is reported to have become established in Costa Rica after 1990 (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). Currently, however, no information is available regarding the interaction of this exotic species with native vertebrate or invertebrate species in Costa Rica. Herein, we document predation on the exotic *H. frenatus* by a native White-fronted Capuchin (*Cebus capucinus*).

On 21 March 2013 at 0730 h an adult capuchin monkey was observed searching for, catching, and eating an adult *H. frenatus* on the patio of the second floor of a residence (09.404678°N, 84.157719°W, datum WGS 84; 140 m elev.) in the town of Manuel Antonio, Costa Rica. Manuel Antonio is located next to Parque Nacional Manuel Antonio, where capuchin monkeys and other animals are frequently seen active on the dense vegetation of the surrounding residences. That morning a group of about 10 capuchin monkeys arrived at the patio of our residence in search of potential food items, an event we had witnessed on four occasions during the previous three days. Two individuals climbed to the ceiling and methodically began to examine every crevice in the ceiling that might potentially harbor prey; in this case, *H.*

PHOTO BY VICENTE MATA-SILVA

FIG. 1. White-fronted Capuchin (*Cebus capucinus*) eating a Common House Gecko (*Hemidactylus frenatus*) in Manuel Antonio, Costa Rica.

frenatus. One monkey succeeded in locating and capturing one gecko from its shelter, and descended to the floor holding its prey with one hand (Fig. 1). First, the monkey ate the tail and a significant portion of the skin covering the trunk and head of the body, and then bit the venter of the gecko and ate some of the internal organs, while the lizard was still alive. After nibbling on the gecko for ca. three minutes, another capuchin approached and took the remains of the gecko and disappeared into the surrounding vegetation. At that point, all four limbs and the head of the gecko remained attached to the body, and most of the muscle tissue was intact. The second capuchin found another gecko, but did not succeed in extracting it from its shelter. The learning behavior required for capuchin monkeys to identify the potential habitat (i.e., houses) and microhabitats where the exotic *H. frenatus* is found, and utilized as a prey, is noteworthy. Additionally, predation on *H. frenatus* by a native bird species (the Great-tailed Grackle, *Quiscalus mexicanus*) has been reported in Mexico (Rojas-Gonzalez and Wakida-Kusunoki 2012. Herpetol. Rev. 43:133). To the best of our knowledge, this observation represents the first report of predation on *H. frenatus* by *C. capucinus*.

We thank the Kumar family for their great company during the trip to Costa Rica, and L. W. Porras for his comments on this note.

***HEMIDACTYLUS MABOUIA* (Tropical House Gecko). PREDATION.** *Hemidactylus mabouia* is a gekkonid lizard of African origin, although currently it has a wide distribution in the Neotropics (Kluge 1969. Misc. Publ. Mus. Zool. Univ. Michigan 138:1–78). Despite being associated with anthropogenic environments (Vanzolini et al. 1980. Répteis das Caatingas. Acad. Brasil. Ciências. 161 pp.; Anjos 2008. Nature Conserv. 6:96–207), this species also occurs in natural environments such as the Atlantic Forest, Cerrado, Caatinga, Restingas, Amazon rainforest, and occurs on islands of the Brazilian coast (Rocha and Bergallo 2011. Braz. J. Biol. 71:447–450). There are few studies conducted on the natural history and ecological interactions of *H. mabouia* (Howard et al. 2001. Caribb J. Sci. 37: 285–288). Diniz 2011 (Herpetol. Notes 4:357–358) and Lanschi and Ferreira 2012 (Herpetol. Rev. 43:133–134) reported predation events involving *H. mabouia* and the orb-weaver spider *Nephilengys cruentata* (Nephilidae) and a hunting spider (Ctenidae), respectively. Here we report an interaction of predation on *H. mabouia* in the Rppn Fazenda Bulcão (19.3119°S, 41.0504°W; elev. 255 m) at Aimorés municipality, Minas Gerais state, southeastern Brazil.

FIG. 1. Lycosid spider feeding on a *Hemidactylus mabouia*, in Aimorés, Minas Gerais, southeastern Brazil.

On 5 June 2012 at 1746 h one of us (LM) observed a lycosid spider (29 mm, cephalothorax + abdomen length) on leaf litter attached to and feeding on a juvenile of *H. mabouia* (SVL = 50.5 mm). The spider bit the prey and remained attached to it until the lizard's death, this process lasting approximately 30 minutes. The family Lycosidae, typically referred to as wolf spiders, is one of the most diverse groups of spiders, with 2393 currently described species in 120 genera (Platnick 2013. The World Spider Catalog. Version 12.0 www.research.amnh.org, accessed 8 January 2012). It comprises mainly hunting spiders that occur in significant numbers in virtually every terrestrial habitat. This report contributes to the knowledge of predation interactions of the non-native lizard *H. mabouia* by native spiders in Brazil, and also suggesting that spiders of different guilds, such as orb-weavers (*Nephilengys cruentata)* and hunting spiders (Ctenidae, Lycosidae) may represent a potential mortality source for populations of this gekkonid.

We thank the Instituto Terra for the logistical support.

***LEPOSTERNON MICROCEPHALUM*. PREDATION.** *Leposternon* is a very specialized genus of Amphisbaenidae (Gans 1974. Biomechanics: an Approach to Vertebrate Biology. J. B. Lippincott, Philadelphia. x + 261 pp.) with a broad distribution in South America (Gans 2005. Bull. Amer. Mus. Nat. Hist. 289:11–30), including Atlantic Forest areas in Southeastern Brazil. *Leposternon microcephalum* is common prey for some terrestrial snakes, especially *Micrurus* spp. (Marques and Sazima 1997. Herpetol. Nat. Hist. 5:88–93), but it is typically not known to be preyed upon by birds. Here we report on a specimen of *L. microcephalum* being caught and consumed by a White-necked Hawk (*Amadonastur lacernulatus*) (Fig. 1), an endemic and threatened species of the Brazilian Atlantic Forest (and so only photographed, not collected) (Thiollay 1994. *In* del Hoyo et al. [eds.], Handbook of the Birds of the World. Vol. 2, pp. 52–205. Lynx Edicions, Barcelona). The predation event was observed by one of us (HR) at Jardim Botânico do Rio de Janeiro, Brazil (the Botanical Garden at Rio de Janeiro City, Brazil; 43.2290°W, 22.9688°S, WGS84; elev. 50 m) at 0900 h on 3 June 2012. The identification of *L. microcephalum* was possible through the pholidosis observed by a specialist (JDBF) and available data on the known distributions of amphisbaenian

species. The photograph in Fig. 2 shows the hawk detaching the amphisbaenian skin from adjacent musculature to eat only the exposed flesh. To our best knowledge, this is the first record of such a behavior for an amphisbaenian predator. Bird predators of amphisbaenians are considered mainly as opportunistic. Zamprogno and Sazima (1993. Herpetol. Rev. 24:82–83) reported four birds of prey as predators of *L. wuchewreri*: Turkey Vulture (*Cathartes aura*), Crested Caracara (*Caracara plancus*), Yellow-Headed Caracara (*Milvago chimachima*), and an unidentified species of hawk (*Buteo* sp.). Additional reports of birds as predators of amphisbaenians include: Southern Lapwing (*Vanellus chilensis*) (Gans 1971. Amer. Mus. Nov. 2475:1–32) and Maguari Stork (*Ciconia maguari*) (Tozetti et al. 2011. Panamjas 6:65–67), which had specimens of *Mesobaena huebneri* and *Amphisbaena trachura* in their stomachs, respectively; chickens and the Roadside Hawk (*Rupornis magnirostris*) feeding on *Amphisbaena* (*darwini*) *heterozonata* (Gallardo 1967. Ciencia e Investigación 23:406–411); chickens feeding on *Amphisbaena* (=*Bronia*) *bedai* (Vanzolini 1991. Pap. Avul. Zool. 37:347–361). However, the present record suggests some specialization of *A. lacernulatus*, regarded as a "ground searcher" species, for its skill in separating and rejecting the skin of *L. microcephalum* before swallowing the head and body. *Amadonastur lacernulatus* is apparently a broad generalist, its recorded prey items including snakes, mammals, birds and invertebrates (mainly arthropods) (Thiollay, *op. cit.*).

FIG. 1. *Leposternon microcephalum* caught by a White-necked Hawk (*Amadonastur lacernulatus*).

FIG. 2. Hawk's behavior of detaching the skin of *L. microcephalum* from adjacent musculature to eat only the exposed flesh.

This is the first documentation of the consumption of an amphisbenian by *A. lacernulatus*.

We thank Paulo Dias for one of the photos, Luciano Almeida for encouraging the publication of this note and Luiz P. Gonzaga for comments on the text.

***MABUYA FRENATA, M, MACRORHYNCHA*. TAIL BIFURCATION.** Bifurcation in lizards is the result of abnormal tail regeneration following autotomy. This phenomenon is considered rare, and has been reported in lizard species of different families (e.g., Brindley 1894. J. Bombay Nat. Hist. Soc. 9:30–33; Colwell 1992. Herpetol. Rev. 23:118; Gogliath et al. 2012. Herpetol. Rev. 43:129; Kumbar and Ghadage 2011. Herpetol. Rev. 42:94). However, such reports usually only mention isolated cases, and the frequency of occurrence of this phenomenon within lizard populations is mostly unknown. In skinks, tail bifurcation has been known to occur in few species, including the North American *Plestiodon egregius* (Taylor 1935. Univ. Kansas Sci. Bull. 23:1–643), *P. fasciatus* (Scott 1982. Herpetol. Rev. 13:46; McKelvy and Stark 2012. Herpetol. Rev. 43:138), *P. anthracinus* (Walley 1997. Bull. Maryland Herpetol. Soc. 33:178–180), and *P. inexpectatus* (Mitchell et al. 2012. Herpetol. Rev. 43:650), the Australian *Liopholis* (=*Egernia*) *whitii* (Hickman 1960. Pap. Proc. R. Soc. Tasmania 94:111–118), and the African *Trachylepis punctatissima* (=*Mabuya striata punctatissima*) (see Plate 1 in Broadley 1977. Occ. Pap. Nat. Mus. Monum. Rhodesia B 6:45–79). The present note reports cases of tail bifurcation in the Neotropical skinks *Mabuya frenata* and *M. macrorhyncha*, observed in specimens housed at the reptile collection of the Museu Nacional, Rio de Janeiro (MNRJ).

Three adult specimens of *Mabuya frenata* collected by DV in an area of rock outcrops (22.933333°S, 46.919167°W) in Valinhos, state of São Paulo, Brazil, expressed tail bifurcation. Two of them, a male (MNRJ 6727; SVL = 71.6 mm) and a female (MNRJ 6728; SVL = 84.4 mm), were collected on 19 December 1993; the male had an original (non-regenerated) portion of tail 51.6 mm long, followed by a regenerated portion extending 18 mm before bifurcating into two sub-equal tips about 10 mm long each. The female had 30 mm of original tail followed by a regenerated portion extending to 31.4 mm before bifurcating into a smaller lateral (7 mm) and a larger (14 mm) axial branch. In the third specimen, an adult male (MNRJ 6800; SVL = 66 mm) collected on 21 March 1994, the original portion of the tail extended 8 mm from the cloaca, then a regenerated portion extended to 10 mm and then bifurcated into a left and a right branch (respectively, 47.8 mm and 37.6 mm long) (Fig. 1). On the left branch, 17 mm from the tip, a second tip (1.7 mm long) was present (Fig. 1), suggesting that another bifurcation could result if it kept growing. The right branch showed evidence of having been broken and re-regenerated.

One specimen of *M. macrorhyncha* (MNRJ 15686) collected in the "restinga" of Barra de Maricá (22.960556°S, 42.862222°W), state of Rio de Janeiro, Brazil, on 30 April 1992 also expressed tail

FIG. 1. Adult male of *Mabuya frenata* (MNRJ 6800) with tail bifurcation. The arrow indicates a second tip growing from the left tail branch.

FIG. 2. Adult male of *Mabuya macrorhyncha* (MNRJ 15686) with tail bifurcation.

bifurcation. The specimen, an adult male (SVL = 66.3 mm), had an original tail portion of 41.3 mm long. The regenerated portion extended 38 mm and then bifurcated into left (20.7 mm long) and right (24.7 mm long) branches (Fig. 2).

It is interesting that, in all cases above, bifurcation apparently occurred after a secondary break of an already regenerated tail portion. In one of the cases (MNRJ 6800), the two branches of the bifid tail were considerably long (each being more than half the total length of the tail, which was as long as the lizard's head and body), indicating that this particular animal was not substantially impaired by this anomaly. This same specimen had a third tail tip which, had it kept growing, could have resulted in a trifid tail (which could possibly result in greater impairment for its mobility).

Van Sluys et al. (2002. Stud. Neotrop. Fauna Environ. 37:227–231) examined 216 individuals of *M. frenata* from Valinhos, São Paulo, and found evidence of tail regeneration in 178 of them (including the three specimens mentioned above). Thus, the frequency of tail bifurcation as a consequence of regeneration can be estimated as 1.7% (3/178) in that population. For the population of *M. macrorhyncha* from Maricá, Rio de Janeiro, D. Vrcibradic (*in* Van Sluys et al., *op. cit.*) found that 78.3% (i.e., 83) of the 106 individuals examined had regenerated tails (including MNRJ 15686). This gives an estimated frequency of bifurcation of 1.2% (1/83), which is similar to that of *M. frenata* from Valinhos. These are, to our knowledge, the first published estimates of the frequency of tail bifurcation in any species of Neotropical lizards.

DAVOR VRCIBRADIC (e-mail: davor@centroin.com.br) and **JULIA NIEMEYER** (e-mail: julia.niemeyer@gmail.com), Departamento de Zoologia, Universidade Federal do Estado do Rio de Janeiro, Av. Pasteur 458, Urca, 22240-290, Rio de Janeiro, RJ, Brazil.

***NOROPS FUSCOAURATUS* (Slender Anole). PREDATION.** *Norops fuscoauratus* is a small arboreal anole, active in the shade during the day, but early in the day can be seen briefly exposed to the sun. Individuals are often observed sleeping at night on leaves or on the ends of branches (Bannerman et al. 2001. Mamirauá: A Guide to the Natural History of the Amazon Flooded Forest. Instituto de Desenvolvimento Sustentável Mamirauá, Tefé, Brazil. 175 pp.; Duellman 2005. Cusco Amazónico, the Lives of Amphibian and Reptiles in an Amazonian Rainforest. Comstock Books in Herpetology, Ithaca, New York. 433 pp.; Vitt et al. 2003. Can. J. Zool. 81:142–156). I am unaware of any reports of predation on *N. fuscoauratus* by an arachnid. I report here an instance of predation on *N. fuscoauratus* by an actenid spider (*Ctenus* sp.).

During a herpetofaunal survey conducted for SINCHI Institute on 15 September 2010 in Colombian Amazonian region (location troche tres Salados, Resguardo Indigena Uitora, municipality of Solano, Caquetá state, southeast Colombia; 0.172°N, 74.651°W; WGS84 datum Bogota), I observed an actenid spider *Ctenus* sp. feeding on a juvenile individual of *Norops fuscoauratus* (SLV 28 mm). The predation event occurred at 2253 h in a trail in the secondary Amazonian rainforest (Fig. 1), the attack on the anole was not observed. The spider may have encountered the anole at night while it was asleep. I found the spider and anole on the leaf of a shrub at 120 cm above the forest floor.

Records of *Ctenus* spiders preying upon vertebrate taxa available in the literature are mainly on anurans in the Amazonian region (Menin et al. 2005. Phyllomedusa 4:39–47) and in the Atlantic Forest of southeast Brazil (Barbo et al. 2009. Herpetol. Notes 2:99–100; Centeno 2009. Diversidade e Uso de Ambiente Pelos Anfíbios e Répteis de São Sebastião, Ilhabela, SP. Unpubl. Master's thesis. Universidade de São Paulo, Brazil). Barbo et al. (*op. cit.*) suggested that these spiders could be important predators of the abundant arboreal and leaf litter-dwelling species, but detailed studies are needed in order to support this hypothesis.

The record presented here increases our knowledge of the relationship between spiders and reptiles and the existence of

FIG. 1. Predation of juvenile individual of the anole *Norops fuscoauratus* by the ctenid spider *Ctenus* sp.

important trophic connections between these groups. This field work was supported by Amazon Institute of Scientific Research SINCHI.

GUIDO F. MEDINA-RANGEL, Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Apartado Aéreo 7495, Bogotá D. C., Colombia; e-mail: guidofabianmedina@gmail.com.

***PHOENICOLACERTA LAEVIS* (Lebanon Lizard). REPRODUCTION.** *Phoenicolacerta laevis* is known from parts of Turkey, Syria, Lebanon, Israel, and Jordan (Uetz 2013. The Reptile Data base, http://www.reptile-database.org., accessed 15 January 2013). There are anecdotal reports on *P. laevis* reproduction consisting of clutch sizes of 2–6 eggs in Turkey (Baran and Atatür 1998. Turkish Herpetofauna [Amphibians and Reptiles]. Publ. Bd. Minis. Environ, Ankara. 214 pp.) and 5–8 eggs in Jordan (Disi et al. 2001. Amphibians and Reptiles of the Hashemite Kingdom of Jordan. Edition Chimaira, Frankfurt am Main. 408 pp.). In Israel, there are two reports of 2–7 eggs (mean = 4 .5) (Frankenberg and Werner 1992. Herpetol. J. 2:7–18) and 2–5 eggs deposited March through May (Bar and Haimovitch 2011. A Field Guide to Reptiles and Amphibians of Israel. Pazbar Ltd., Herzliya, Israel. 245 pp.). The purpose of this note is to provide additional information on reproduction of *P. laevis* from a histological examination of gonadal material from Israel.

A sample of 24 *P. laevis* was examined, consisting of 9 males (mean SVL = 62.2 mm ± 3.9 SD; range = 58–68 mm), 12 females (mean SVL = 62.6 mm ± 5.9 SD, range = 53–72 mm), 2 subadult females (mean SVL = 46.5 mm ± 2.1 SD; range = 45–48 mm) and 1 unsexed juvenile (SVL = 36 mm) collected 1949 to 1998 in Israel and deposited in the Zoological Museum of Tel Aviv University (TAUM), Tel Aviv, Israel by district: Haifa District: 4417, 12237, 13105, 13795; Northern District TAUM 1063, 1065, 1066, 1182–1184, 5374, 6176, 8622, 11458, 11459, 14375, 15484, 15761, 15764; Tel Aviv District: 1059, 2174, 4748, 5541,16437.

TABLE 1. Monthly stages in the testicular cycle of 9 adult *Phoenicolacerta laevis* from Israel.

Month	N	Regressed	Spermiogenesis
March	2	0	2
April	2	0	2
May	2	0	2
August	1	1	0
November	2	0	2

TABLE 2. Monthly stages in the ovarian cycle of 12 adult *Phoenicolacerta laevis* from Israel.

Month	N	Quiescent	Early yolk deposition	Enlarged follicles > 4 mm	Oviductal eggs
March	2	0	1	0	1
April	1	1	0	0	0
May	1	0	0	1	0
June	1	0	0	0	1
July	3	0	1	1	1
September	2	1	0	0	1
November	1	1	0	0	0
December	1	1	0	0	0

A small slit was made in the left side of the abdomen and the left testis was removed from males and the left ovary was removed from females for histological examination. Enlarged ovarian follicles (> 4 mm) or oviductal eggs were counted *in situ*. No histology was performed on them. Removed gonads were embedded in paraffin. Sections were cut at 5 µm and stained by Harris' hematoxylin followed by eosin counterstain. Histology slides are deposited at TAUM.

Two stages were noted in the testicular cycle: 1) regressed = post breeding (seminiferous tubules contain spermatogonia and Sertoli cells); 2) spermiogenesis (seminiferous tubules lined by clusters of sperm or metamorphosing spermatids). Monthly stages in the testicular cycle are in Table 1. The smallest reproductively active male (spermiogenesis) measured 58 mm SVL (TAUM 2174) and was collected in April.

Four stages were noted in the ovarian cycle (Table 2); (1) quiescent, (no yolk deposition); (2) early yolk deposition (vitellogenic granules in the cytoplasm); (3) enlarged follicles (> 4 mm); (4) oviductal eggs. The smallest reproductively active female measured 53 mm (3 oviductal eggs) (TAUM 5374) and was collected in September. Two reproductively inactive females from November (SVL = 45 mm, TAUM 15764) and SVL = 48 mm, TAUM 15484) were considered as subadults. Another subadult of undetermined sex (SVL = 36 mm, TAUM 16437) was collected in September and may have been born earlier the same year. Mean clutch size for 5 females was 3.6 ± 1.1 SD, range = 2–5. There was no evidence (oviductal eggs and concomitant yolk deposition in the same female) to suggest *P. laevis* females produced multiple clutches in the same reproductive season. However, there is sufficient time for production of multiple clutches as reproductively active females were collected from March to September, excluding April (N = 1) and males produce sperm starting in November. Multiple egg clutches are produced by *P. laevis* in Jordan (Disi et al. *op. cit.*). Males of the congener *A. schmidti* in Saudi Arabia also exhibited spermiogenesis in November (Al-Johany and Spellerberg 1988. J. Arid. Environ.15:197–207).

I thank Shai Meiri (TAUM) for permission to examine *P. laevis*, Erez Maza for facilitating the loan and the National Collections of Natural History at Tel Aviv University for providing samples of *P. laevis* for this study.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***PLESTIODON LAGUNENSIS* (San Lucan Skink). REPRODUCTION.** The biology of *Plestiodon lagunensis* is summarized in Beaman et al. (2004. Cat. Am. Amphib. Rept. 792:1–3). Here we report additional information on the timing of reproduction in *P. lagunensis*.

Specimens were examined from the San Diego Natural History Museum (SDNHM 66870, 68703–704, 68706) and the University of Arizona (UAZ 22977–986, 23386). Eight males (mean SVL = 49.8 mm ± 4.7 SD, range = 40–56 mm), 6 females (mean SVL = 50.0 mm ± 5.8 SD, range = 43–59 mm), and 1 neonate (SVL = 26 mm SVL) were examined. One gonad was removed for histological examination. Histological sections were removed and embedded in paraffin, cut at 5µm, mounted on glass slides and stained by Harris' hematoxylin followed by eosin counterstain.

The only stage noted in the ovaries of *P. lagunensis* was quiescence in which no yolk deposition occurred in the follicles. The female samples were from June (N = 1), July (N = 5), and October (N = 1). Three stages of the testicular cycle were observed: 1) regressed (i.e., seminiferous tubules contain spermatogonia

and sertoli cells), 2) early recrudescence (i.e., slightly increased cellularity due to dividing spermatogonia and the appearance of some primary spermatocytes), and 3) recrudescence (i.e., marked increased cellularity with abundant primary spermatocytes). The male samples were from June (N = 3: regressed), July (N = 2: early recrudescence), and October (N = 1: regressed, N = 2: recrudescence).

Our data suggest, along with the collection of a neonate in July, and the observation of hatchlings in mid-July and juveniles from August to November by Grismer (2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands in the Sea of Cortes. Univ. California Press, Berkeley. 399 pp.) that *P. lagunensis* appears to breed in spring and early summer. The males of *P. lagunensis* from October, which exhibited recrudescence, would have likely undergone spermiogenesis the following spring. These observations suggest that fall recrudescence in *P. lagunensis* is similar to other North American lizards in the genus *Plestiodon* (*P. gilberti*: Goldberg 2009. Bull. Maryland Herpetol. Soc. 45:28–32; and *P. skiltonianus*: Goldberg 2005. Texas J. Sci. 57:295–301). Other North American lizards that breed in the spring also exhibit fall recrudescence (Goldberg. 1974. Copeia 1974:176–182; Goldberg1975. Am. Midl. Nat. 93:175–185; Goldberg 1977. J. Herpetol. 11:31–35).

We thank B. Hollingsworth (SDNHM) and P. Reinthal (UAZ) for permission to examine specimens.

BEAMAN**, Section of Herpetology, Natural History Museum of Los Angeles County, Los Angeles, California 90007, USA (e-mail: heloderma@roadrunner.com); **JEANETTE ARREOLA**, Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: jarreola@poets.whittier.edu).

***SCELOPORUS AENEUS* (Bunchgrass Spiny Lizard). DIET.** Many species of *Sceloporus* lizards are considered insectivorous (Lemos-Espinal and Smith 2007. Amphibians and Reptiles of Chihuahua. Universidad Nacional Autónoma de México y Comisión Nacional para el Uso de la Biodiversidad, 613 pp.; Smith 1939. Zool. Ser. Field Mus. Nat. Hist. 26:1–397), with a few documented cases of herbivory (Méndez de la Cruz et al. 1992. Southwest. Nat. 37:349–355) and cannibalism (Leyte-Manriquez et al., 2005. Herpetol. Rev. 36: 454; Vega-López and Alvarez 1992. Acta Zool. Mex. 51:1–128).

On 21 May 2010 at the La Malinche volcano in Tlaxcala, Mexico (19.227122°N, 97.2124083°W, WGS84, 2700 m elev.), we found a female *Sceloporus aeneus* (SVL = 57.31 mm; weight = 4.4 g) perched on a rock in direct sunlight at 1230 h. During capture we discovered lizard toes protruding from outside of its mouth; we extracted the prey item with tongs. Upon extraction we found a partially digested juvenile of *Sceloporus grammicus* (SVL = 33.74 mm; weight = 1 g). The SVL of the prey corresponded to 58% total length and to 22% total weight of the female *S. aeneus*. *Sceloporus aeneus* is generally considered an insectivorous opportunistic species (Urbano-Lozano 2008. Unpubl. Bachelor's Thesis, Universidad Nacional Autónoma de México, FES-Iztacala). Thus, we document the first record of *S. aeneus* feeding on a lizard and show that this species has the capability to feed on proportionally-sized prey. This could be an uncommon event induced by malnutrition subsequent to oviposition, when females lose a large portion of body mass.

C.P. 04510 (e-mail: vhjimenezarcos@yahoo.com.mx).

***SCELOPORUS LINEATULUS* (Isla Santa Catalina Spiny Lizard). DIET AND ACCIDENTAL MORTALITY.** *Sceloporus linealtulus* is endemic to Isla Santa Catalina, Baja California Sur, Mexico. Virtually nothing is known of the natural history of *S. lineatulus* (Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands of the Sea of Cortéz. Univ. California Press, Berkeley. 339 pp.). On 26 May 2011 several specimens of *S. lineatulus* were observed at the base of a large *Pachycereus pringlei* (Cardón Cactus) feeding on the seeds of the cactus's fallen fruit. Closer observation revealed a deceased individual whose head had become stuck in the seed pod while feeding, and presumably succumbed to the midday heat. To our knowledge this is the first record of the natural diet of *S. lineatulus* and subsequent mortality by seed pod.

We thank the many people of Mexico who assisted us in the field, SEMARNAT, and the Mexican government who granted us access to their country, its wonderful herpetofauna, and ecological diversity. All research and collecting was performed under the authority of SEMARNAT scientific research permit oficio num. SGPA/DGVS/03804 issued to IR.

FIG. 1. Desiccated carcass of *Sceloporus linneatulus*, mortality by seed pod, Isla Santa Catalina, Baja California Sur.

***SCELOPORUS UNDULATUS* (Eastern Fence Lizard). FEEDING BEHAVIOR.** Eastern Fence Lizards obtain a substantial portion of their diet from ants, particularly as juveniles (Parker 1994. Copeia 1994:136–152). *Solenopsis invicta* (Red-imported Fire Ant; hereafter fire ant) was introduced through the port of Mobile, Alabama in the 1930s and has now invaded much of the southeastern United States (Wojcik et al. 2001. Amer. Entomol. 47:16–23). It is likely that Eastern Fence Lizards consume fire ants while foraging and fire ants are considered a novel, toxic prey as they can sting fence lizards when eaten and ultimately cause death in smaller individuals (Langkilde and Friedenfelds 2010. Wildl. Res. 37:566–573). To date, all observations of fence lizards consuming

fire ants of which I am aware occurred when individuals were under attack, or possibly opportunistically (e.g., Boronow and Langkilde 2010. J. Exp. Zool. 331A:17–23; Robbins and Langkilde 2012. J. Evol. Biol. 25:1937–1946). Moreover, Robbins and Langkilde (*op. cit.*) indicate uncertainty regarding whether fence lizards consume fire ants during regular foraging activity.

I observed a juvenile Eastern Fence Lizard (SVL = 22 mm) on top of an active fire ant mound on 10 October 2012 between 1730 h and 1759 h at the Joseph Jones Ecological Research Center in Newton, Georgia, USA. I observed and recorded the lizard actively moving on the mound to forage for 30 minutes and watched it consume three fire ants. Prior to this observation, on 12 September and 13 September 2012 at 1823 h and 1938 h, respectively, I observed an additional juvenile lizard on top of an active fire ant mound and, after monitoring the individual for 10 minutes, I observed the lizard consume one fire ant at 1833 h. A third juvenile lizard (SVL = 39 mm) was seen basking on an active fire ant mound by S. Greenspan on 8 October 2012 at 1118 h and I observed two more fence lizards basking on active fire ant mounds on 8 November 2012 at 1110 and 1445 h, but we did not stop to monitor their behavior. My observations indicate that Eastern Fence Lizards consume fire ants during regular foraging, rather than just opportunistically, and will use fire ant mounds as foraging sites. If fire ant consumption can lead to juvenile mortality, as found by Langkilde and Friedenfelds (*op. cit.*), this behavior could have a considerable influence on fence lizard population dynamics.

ANDREA K. LONG, University of Florida, Department of Wildlife Ecology and Conservation, 110 Newins-Ziegler Hall, PO Box 110430, Gainesville, Florida 32611, USA; e-mail: aklong@ufl.edu.

***SCELOPORUS UNIFORMIS* (Yellow-backed Spiny Lizard). DIET.** *Sceloporus uniformis*, recently elevated to species from within the *S. magister* complex (Crother [ed.] 2012. SSAR Herpetol. Circ. 39:1–92; Leaché and Mulcahy 2007. Mol. Ecol. 16:5216–5233), is a robust spiny lizard of the Mojave and Great Basin deserts. As with most *Sceloporus*, the species appears to be a generalist insectivore, feeding on ants, beetles, caterpillars, and other locally abundant arthropods as well as the occasional lizard (Knowlton and Nye 1946. Utah J. Econ. Entomol. 39:546; Parker and Pianka 1973. Herpetologica 29:143–152; Vitt and Ohmart 1974. Herpetologica 30:410–417). Here we document a novel insect prey of *S. uniformis*, ladybird beetles (Coleoptera: Coccinellidae). This observation is noteworthy because ladybird beetles are chemically defended (King and Meinwald 1996. Chem. Rev. 96:1105–1122), and despite being conspicuous and often abundant, they are noticeably absent from the diet of nearly all North American lizards.

On 5 May 2011, along the eastern point of Anaho Island National Wildlife Refuge in Pyramid Lake, Washoe Co., Nevada, USA (39.94937°N, 119.49952°W, NAD83; 980 m elev.), we noosed several *S. uniformis*. While handling these lizards, two adult males (SCUN AI.005, SVL 85 mm; SCUN AI.008, SVL 95 mm) regurgitated their stomach contents, which were largely Seven-spotted Ladybird Beetles (*Coccinella septempunctata*). One lizard (SCUN AI.005) regurgitated ~17 ladybird beetles, the other (SCUN AI.008) ~12 ladybirds. The lizards were measured, marked and released, and the stomach contents retained for verification.

The absence of coccinellids in the diet of most lizards is striking, given the ubiquity, abundance, and visibility of these insects. Coccinellids possess formidable chemical defenses that may deter most arthropod and vertebrate predators (Happ and Eisner 1961. Science 134:329–331; Marples 1993. Chemoecology 4:33–38), including pyrazines that give an unpleasant odor (Moore et al. 1990. Chemoecology 1:43–51) and various toxic or distasteful alkaloids that ladybirds can exude from their haemolymph when threatened (King and Meinwald 1996, *op. cit.*). These chemicals are particularly effective against some birds, even inhibiting growth (Marples 1993, *op. cit.*). However, other vertebrates appear less affected; many amphibians seem tolerant of coccinellid toxins, and some bufonids and ranids consume significant quantities of ladybirds (Sloggett 2012. Insects 3:653–667). Among North American lizards, coccinellids have only been found as apparently accidental food items in the anguid *Elgaria multicarinata* (Cunningham 1956. Herpetologica 12:225–230) and xantusiid *Xantusia vigilis* (Brattstrom 1952. Copeia 1952:168–172), as well as the phrynosomatids *Uta stansburiana* (Knowlton and Thomas 1936. Copeia 1936:64–66) and *S. occidentalis* (Johnson 1965. Herpetologica 21:114–117). Only two phrynosomatids, *S. undulatus* and *S. graciosus*, appear to include ladybirds as a meaningful component of their diets, taking coccinellids with the same frequency as other similar-sized beetles (Johnson 1966. Am. Midl. Nat. 76:504–509; Knowlton 1948. Herpetologica 4:151; Knowlton and Thomas 1936, *op. cit.*; Knowlton et al. 1946. Utah J. Econ. Entomol. 39:382–383; Toliver and Jennings 1975. Southwest. Nat. 20:1–11). We suspect that our case of ladybird predation is purely incidental because earlier diet analyses of lizards in the *S. magister* complex have failed to turn up coccinellids as prey (e.g., Knowlton and Nye 1946, *op. cit.*; Parker and Pianka 1973, *op. cit.*; Vitt and Ohmart 1974, *op. cit.*), and in our examination of several *S. uniformis* stomachs from Anaho Island we have never observed coccinellids. Nevertheless, it remains unclear whether the toxins in ladybirds are effective deterrents to lizard predation in general, and whether some lizard groups (e.g., *Sceloporus*) have evolved tolerance or other means of resistance to these defenses.

We thank D. Withers of the USFWS for permits and access to Anaho Island, and M. L. Forister for verifying the beetles.

***TROPIDURUS HYGOMI* (Reinhardt's Lava Lizard). COURTSHIP BEHAVIOR.** *Tropidurus hygomi* is a heliothermic, generalist lizard, endemic to northeastern Brazil in restinga ecosystems of the north coast of Bahia from Salvador to the state of Sergipe (Rodrigues 1987. Arq. Zool., S. Paulo 31[3]:105–230). There are no records concerning the courtship behavior of the species.

On 13 March of 2013, around 0900 h, we recorded courtship behavior, followed by an attempted mating, between two *T. hygomi* within restinga of Reserva Imbassaí (12.481616°S, 37.957193°W; datum WGS 84) using a Samsung WB100 digital camera. We kept a distance of 3 m from the lizards during filming. Air and substrate temperature were 36.6°C and 28°C, respectively. The adult female was foraging among leaf litter. When the female noticed the presence of the male, she elevated her tail (Fig. 1). Such behavior in some lizard species is performed during courtship or as a defensive action towards predators (Dial 1986. Amer. Nat. 127:103–111). The female then waved the tail

FIG. 1. Tail display by a female *Tropidurus hygomi* directed towards a male of the same species.

FIG. 1. Use of aphid gall by *Takydromus smaragdinus* on Okinawajima Island, Japan.

laterally for approximately one second and also raised her pelvis. The male, larger than the female, was at approximately 3 m away and approached her, directing his head to her cloaca region. The female refused copulation, moving away from the male, who then bit her right hind limb. The male stayed in the same place with his body stretched forward, watching her.

After the first attempt, there was a second attempt after three minutes. The female was on a dead bromeliad and raised the tail again and waved it laterally. Then, the female climbed into a bush, followed by the male, at which time we were no longer able to continue observation.

***TAKYDROMUS SMARAGDINUS* (Green Grass Lizard). OVERWINTER SHELTER.** *Takydromus smaragdinus* is a diurnal grass lizard occurring in subtropical forests and is endemic to the Central Ryukyu Islands, Japan (Ota et al. 2002. Biol. J. Linn. Soc. 76:493–509). Because the lizards are exposed to great predation pressures by a variety of species, including avian, mammalian, and snake predators, they exhibit several defensive behaviors, including sleeping and resting site selection. For example, during the active season (early spring to early winter), this lizard utilizes leaves located at the tips of thin branches as a nighttime sleeping site (unpubl. data), and such sleeping site selection by small lizards is believed to aid in nocturnal predation avoidance (see references in Ikeuchi et al. 2012. Current Herpetol. 31:107–116). Herein, we report that this lizard exploits insect galls as shelters during the inactive season. In winter, *T. smaragdinus* enters a temporary state of torpor, therefore, it has seldom been observed active during this time of year in the bushes, which are its natural habitats both day and night during the active season. During daylight hours, we collected seven galls, which had previously been abandoned by parasitic aphids, *Sinonipponaphis monzeni*, from five individual host plants (*Distylium racemosum*) in January 2013. The trees were located at the edge of the forests on Okinawajima Island (26.755°N, 128.297°E). In three out of the seven galls, we found two male lizards (SVL = 42.0 mm; head width = 5.0 mm; SVL = 32.9 mm; head width = 4.5 mm) and one female (SVL = 63.5 mm; head width = 5.7 mm). The largest diameters of three galls were 63.6, 56.4, and 55.3 mm, and the diameters of holes on these galls were 12.9, 12.1, and 11.8 mm, respectively. Galls were located at the heights of 4.5, 5.5, and 4.5 meters from the ground. Compared to the inhabited galls, there were bigger holes on the four galls that were not utilized by the grass lizards (diameters from 13.5 mm to 37.8 mm), but there appeared to be no differences in gall size and distance from the ground. Nocturnal mammals and snakes, which are common arboreal lizard feeders in the study area, would not have access to the lizards within these galls due to the small entrances. This shelter also protects the lizards against diurnal predators, such as birds, while lizards on the leaves at the tip of branches would present easy targets for them. In *T. smaragdinus*, insect galls potentially serve as optimum shelters against predators during both daytime and nighttime, although the number of galls might not be enough compared to the number of lizards in the area and they can only be utilized after autumn when the aphids leave. This is a unique example of a secondary usage of shelter previously utilized by another animal.

KOJI MOCHIDA, Tropical Biosphere Research Center, University of Ryukyus, Nishihara, Okinawa 903-0213, Japan (e-mail: kj.mochida@gmail.com); **TOMOHIKO SHIMADA** and **SHIZUKA TSUNEKI**, Department of Science, Aichi University of Education, Igaya, Kariya, Aichi 448-8542, Japan.

***TROPIDURUS HISPIDUS* (Peters' Lava Lizard). SAUROPHAGY.** *Tropidurus hispidus* is a widely distributed Neotropical lizard, occurring from eastern Maranhao and eastern Para, and from enclaves of open vegetation north of the Amazon river, in Roraima, Brazil, to southern French Guiana, Suriname, Guyana, and Venezuela (Ávila-Pires 1995. Zool. Verh. Leiden. 299:1–706). The diet of *T. hispidus* is composed mainly of arthropods, including ants, beetles, insect larvae, and termites, as well as plant material, including leaves, flowers, and fruits (Kolodiuk et al 2010. South Am. J. Herpetol. 5:35–44; Ribeiro and Freire 2009. Herpetol. Rev. 40:228–228). The ingestion of small vertebrates, such as frogs (Ribeiro and Freire 2009, *op. cit.*) and other lizards (Van Sluys 2004. J. Herpetol. 38: 606–611; Vitt et al. 1996. J. Trop. Ecol. 12:81–101) may occur occasionally. We report here on the

ingestion of a lizard previously unrecorded as prey for *T. hispidus* in the Forest Fragment of the University of Amapá, in the municipality of Macapá, Brazil.

During an ecological study of a community of lizards in the Forest Fragment (0.006283°S; 51.08265°W; datum WGS84), a total of 25 stomachs were analyzed. A dactyloid lizard, *Norops auratus* (SVL = 46.0 mm; total length = 63.0 mm; volume = 18.5 mm^3) was found in the stomach contents of an adult female *T. hispidus* (SVL = 81.3 mm) captured on 26 September 2011, in addition to Hymenoptera, Coleoptera, Orthoptera, and plant matter (fruits and leaves). The voucher specimen of *T. hispidus* was deposited in the Collection of Laboratory of Zoology of the Universidade Federal do Amapá, Brazil (CDLABZOO 111). We thank the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for financial support (Process 126528/2011-0). ICMBio provided a permit (Proc. Number 31814-2).

CARLOS E. COSTA-CAMPOS (e-mail: eduardocampos@unifap.br) and **NAZIEL S. SOUZA** (e-mail: souzanaziel@gmail.com), Laboratório de Herpetologia, Departamento Ciências Biológicas e da Saúde, Centro de Biociências, Universidade Federal do Amapá, Campus Marco Zero, 68903-280, Macapá, AP, Brazil.

***TROPIDURUS HYGOMI*. PREDATION.** *Tropidurus hygomi* is one of the few species of reptiles endemic to restinga habitat of coastal Brazil, occurring in discontinuous populations along the coast of Salvador, Bahia state, to Santo Amaro das Brotas, Sergipe (Vanzolini and Gomes 1979. Pap. Avul. Zool. 32:243–259). Data regarding the autecology of this species are lacking (Martins et al. 2010. Biotemas 23:71–75) and interspecific relationships with other species are not well understood, with the exception of a report on juvenile predation by *Ameivula abaetensis* (Dias and Rocha 2004. Herpetol. Rev. 35:398–399). The present note reports a predation event on an individual *T. hygomi* (SVL = 71.49 mm) by a juvenile *Boa constrictor* (total length = 49.00 cm; head length = 30.49 mm; head height = 9.75 mm; head width = 14.09 mm) during a field survey at 1140 h on 12 March 2012 at Costa Azul, Jandaira municipality, Bahia, Brazil (11.6621°S, 37.4818°W; datum WGS84). The predatory behavior occurred under a shrub (*Byrsonima* sp.; height = 320 cm). The specimens were captured by hand, euthanized, and deposited in the collection of the Laboratório de Biologia e Ecologia de Vertebrados, at Universidade Federal de Sergipe (collection permission: 31047-1 - IBAMA/RAN).

RAFAEL BARBOSA DA SILVA VIEIRA, Centro Universitário Jorge Amado, Salvador, Bahia, Brazil (e-mail: scubavieira@hotmail.com); **IGOR RIOS DO ROSÁRIO**, Universidade Federal da Bahia, Salvador, Bahia, Brazil (e-mail: rosario.igor@hotmail.com); **LUIZ EDUARDO DE OLIVEIRA GOMES**, Núcleo Integrado de Estudos em Zoologia, Instituto de Ciências Biológicas, Universidade Católica do Salvador, Salvador, Bahia, Brazil (e-mail: luiz.e.o.gomes@gmail.com); **EDUARDO JOSÉ DOS REIS DIAS**, Laboratório de Biologia e Ecologia de Vertebrados, Departamento de Biociências, Campus Alberto de Carvalho, Universidade Federal de Sergipe, Itabaiana, Sergipe, Brazil (e-mail: ejrdias@hotmail.com).

***UROSTROPHUS VAUTIERI* (Brazilian Steppe Iguana). DIET.** *Urostrophus vautieri* is native to Brazil, occurring in all states of the south and southeast regions (Condez et al. 2009. Biot. Neotrop. 9:157–185; Levandeira-Gonçalves et al. 2007. *In* C. C. de Faria and E. B. V. de Castro [eds.], Ciência e Conservação na Serra dos Órgãos, pp. 137–153. Brasília, Brasil; Souza-Filho 2011. Check List 7:876–877). There are few records of prey items for this species. Prior to this report, arthropods of the orders Orthoptera and Coleoptera have been reported as food items of *U. vautieri* by Sazima and Haddad (1992. *In* L. P. C. Morellato [ed.], História Natural da Serra do Japi: Ecologia e Preservação de uma Área Florestal no Sudeste do Brasil, pp. 212–235. UNICAMP, Campinas), and by Condez et al. (2009, *op. cit.*).

In the current study we analyzed the stomach contents of five specimens of *U. vautieri* (two females: CRLZ 000065, 000256, and three males: CRLZ 000077, 000126, 000152) deposited in the Coleção de Répteis do do Laboratório de Zoologia, Centro Universitário de Lavras (CRLZ) - UNILAVRAS. All specimens are from the Reserva Biológica Unilavras Boqueirão (RBUB) (21.346°S, 44.990°W, datum WGS84; 1250 m elev.) in riparian forest associated with phytophysiognomies of Cerrado, in the municipality of Ingaí, Minas Gerais state, Brazil. We recorded body parts of specimens of arthropods of the orders Coleoptera (thorax, elytra, and abdomen), Hymenoptera (heads of wasps and ants, and wings), Blattodea (legs and abdomen), and Diptera (heads); and remains of shed skin of these specimens of *U. vautieri*. Hymenoptera, Blattodea and Diptera are novel arthropod taxa reported in the diet of this lizard. Ingestion of shed skin by *U. vautieri* has been previously observed by Ribeiro and Sousa (2006. Herpetol. Rev. 37:348–348).

***VARANUS PANOPTES* (Yellow-spotted Monitor). CANNIBALISM.** Intraspecific predation, or cannibalism, is common and widespread in animals, and is important in the ecology and evolution of many species (Polis 1981. Annu. Rev. Ecol. Syst 12:225–251). However, there is limited understanding of the implications of cannibalism for the behavior, ecology, and population dynamics of many species (Hämäläinen 2012. Amer. J. Primatol. 74:783–787).

In reptiles, cannibalism is known from at least 191 species (Mitchell 1986. SSAR Herpetol. Circ. 15; Polis and Myers 1985. J. Herpetol. 19:99–107, and other report since). For the carnivorous monitor lizards, field observations of cannibalism exist for eight of the 53 species (*Varanus bengalensis, V. giganteus, V. gouldii, V. griseus, V. komodoensis, V. rosenbergi, V. salvator,* and *V. storri*), with a further three species engaging in cannibalism in captivity (*V. exanthematicus, V. glebopalma, V. timorensis*) (Auffenberg 1994. The Bengal Monitor, Univ. Press Florida; Bennett 2000. Bull. Chicago Herpetol. Soc. 35:177–180; GéCzy 2009. Biawak 2:61–63; Horn and Schurer, 1978. Salamandra 14: 105–116; King and Green 1979. Copeia 1979: 64–70; reviewed in Mitchell 1986, *op. cit.*; King et al. 1989. Austral. Wildl. Res. 16:41–47; Shine et al. 1996. Biol. Conserv. 77:125–134). The generalized diet of many monitor lizards combined with the ability to swallow large prey items suggests that cannibalism may be more widespread than currently appreciated. Here we present two observations of cannibalism in *Varanus panoptes,* a species in which cannibalism has not been previously recorded.

On 6 May 2012 at approximately 1600 h, a medium-sized male *V. panoptes* (SVL = 40.6 cm; TL = 101.4 cm) was radio-tracked to an

area of open woodland along a permanent wetland at El Questro Wilderness Park in the east Kimberley region of Western Australia (15.980556°S, 127.458889°E). Upon approaching the animal, we noticed a juvenile *V. panoptes* (SVL: 192 mm, TL: 479 mm) in the mouth of the male. The male dropped the juvenile before fleeing a distance of approximately 30 m. The juvenile *V. panoptes* was dead upon discovery and exhibited wounds consistent with being mouthed by another monitor lizard.

On 8 June 2001, we observed a large *V. panoptes* on the bank of the Daly River near Oolloo Crossing, Northern Territory, Australia (14.004391°S, 131.240014°E). The lizard was a male, judging by its size (ca. 60 cm), and was in the act of swallowing a sub-adult *V. panoptes* that was about one-third the size of the cannibal. The head and front legs were inside the larger lizard. The smaller lizard was still struggling, raking at the head of the larger lizard with its hind legs. The larger lizard appeared to be struggling to swallow its prey, and would shake it from side-to-side occasionally. Once the prey stopped struggling, the larger monitor slowly swallowed it until just a portion of tail (ca. 15 cm) was left hanging out of its mouth. At this stage the larger lizard appeared to have difficulty walking, and we did not observe the last portion of the tail being swallowed. During the latter part of the swallowing, a third *V. panoptes* walked past that was a similar size to the one that was eaten.

Although our 2001 observation may reflect scavenging, the prey in our 2012 observation was definitely alive. Moreover, there are observations of *V. panoptes* capturing and eating other monitor species (Christian 1995. Herpetol. Rev. 26:146; Rhind and Doody 2011. Herpetofauna 41:64–65). Benefits of cannibalism not involving offspring or eggs include nutrition, reduction of competition for resources, or reproductive competition (Polis 1981, *op. cit.*). In tropical ecosystems in Northern Australia, *V. panoptes* plays an important role as a key predator and is responsible for the regulation of a number of prey species (Blamires 2004. Copeia, 2004:370–377; Doody et al. 2006. Wildl. Res. 33:349–354; Doody et al. 2009. Anim. Conserv. 12:46–53; Doody et al. 2012a. Herpetol. Rev. 43:339–340; Doody et al. 2012b. Herpetol. Rev. 43:491–492; Doody et al. 2013. Biol. Invas. 15:559–568; Webb and Manolis 2010. Freshwater Crocodile, *Crocodylus johnstoni*, Status Survey and Action Plan. Crocodile Specialist Group, Darwin). Large male *V. panoptes* may likewise consume conspecifics frequently, but our observations are not sufficient to determine the frequency of cannibalism or its costs-benefits in this top predator.

***ZOOTOCA VIVIPARA* (Common Lizard). RECORD WEIGHT.** On 25 June 2011 a very heavy adult female specimen of *Zootoca vivipara* was found on the island of Hiddensee near Vitte (54.563816°N, 13.112562°E) at the German coastline of the Baltic Sea underneath a dry-docked sailing boat. The female *Z. vivipara* reported here weighed 10.0 g (live weight), which makes it the heaviest gravid female specimen of the Common Lizard ever recorded (Fig. 1). The examined *Z. vivipara* measured 157 mm in total length (SVL = 72 mm; tail length = 85 mm). Most adult specimens of *Z. vivipara* express a total length of 110–140 mm with a maximum length of approximately 180 mm (Günther and Völkl 1996. *In* R. Günther [ed.], Die Amphibien und Reptilien Deutschlands, pp. 588–600. Fischer, Jena). Female individuals typically have a SVL measuring between 45 and 70 mm, seldom more than 75 mm (Günther and Völkl, 1996, *op. cit.*). Few reports regarding body weight data have been published for *Z. vivipara.*

FIG. 1 Gravid adult female *Zootoca vivipara* with a record weight of 10.0 g (found on the island of Hiddensee, Germany).

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead). DIET.** *Agkistrodon contortrix* is a widely-distributed viperid species that occurs in the eastern and central United States and northern Mexico. The species' diet is known to include many species of small mammals, birds, snakes, lizards, frogs, salamanders, and invertebrates (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere, Volume I. Cornell University Press, Ithaca, New York. 475 pp.). On 19 April 2012, at 2040 h, a male *A. contortrix* (SVL ca. 63.4 cm; Auburn University Museum [AUM] 39901) was collected injured on State Road 503 near CR 20 in Jasper Co., Mississippi, USA (32.13914°N, 89.06058°W; datum WGS84). The snake died overnight. While curating the specimen, the remains of an adult *Plestiodon inexpectatus* (Southeastern Five-lined Skink; AUM 39902) were found in the stomach. The lizard had been ingested headfirst. To our knowledge, this is the first record of *A. contortrix* consuming *P. inexpectatus* (Campbell and Lamar, *op. cit.*).

We thank Craig Guyer for verifying the records and Scott Peyton for assistance in procuring collecting permits.

BRIAN FOLT (e-mail: brian.folt@gmail.com) and **DAVID LAURENCIO** (e-mail: norops@auburn.edu), Auburn Museum of Natural History, Department of Biological Sciences, 331 Funchess Hall, Auburn University, Alabama 36849, USA.

***BOGERTOPHIS SUBOCULARIS* (Trans-Pecos Ratsnake). OVERWINTERING BEHAVIOR.** Colubrid snakes in North America, especially those inhabiting higher latitudes, typically hibernate during the cold winter months (Ernst and Ernst 2003. Snakes of

the United States and Canada. Smithsonian Inst. Press. Washington, D.C. 680 pp.). However, there is no information reported on the winter behaviors and ecology of *Bogertophis subocularis*. Herein, we report on a radio-tracked female *B. subocularis* (total length = 1070 mm; 215.4 g) over a nine-month period on Indio Mountains Research Station (IMRS) (centered on 30.75°N, 105.00°W; datum WGS84), Hudspeth Co., Texas, USA. The landscape in the study area is represented by typical Chihuahuan Desert scrub. On 27 November 2010, at 1030 h, the female was observed basking outside its overwintering microhabitat site after ingress. The hibernaculum (elev. 1358 m) was located on a northeastern slope of part of the rimrock of Flat Top Mountain (Worthington et al. 2004. Biotic Resources of Indio Mountains Research Station, Southern Hudspeth County, Texas. University of Texas, El Paso. 85 pp.), which was composed of mostly trachyte rocks with sparse vegetation (*Bouteloua* grasses). The snake was visible until 1120 h, after which it went deeper in the hibernaculum. The body temperature of the snake was 13.5°C, and the ambient, substrate, and microhabitat temperatures were 12.5°C, 13.8°C, and 14°C, respectively. The Chihuahuan Desert has broad periods in which temperatures can reach freezing during the winter months, limiting the surface activity of most snakes, such as *B. subocularis*. This is the first documented sighting of *B. subocularis* basking during the the winter months.

ARTURO ROCHA (e-mail: turyrocha@yahoo.com; arocha45@epcc.edu), **VICENTE MATA-SILVA** (e-mail: vmata@utep.edu), **JERRY D. JOHNSON** (e-mail: jjohnson@utep.edu), and **WILLIAM D. LUKEFAHR**, Department of Biological Sciences, The University of Texas at El Paso, El Paso, Texas 79968, USA.

***BOTHROCOPHIAS CAMPBELLI* (Campbell's Toad-headed Pitviper, Víbora Boca de Sapo de Campbell). DIET/OPHIOPHAGY.** The only documented prey item of *Bothrocophias campbelli* is a partly digested rat-sized rodent reported from Ecuador (Freire and Kuch 2000. Herpetol. Rev. 31:45). On 19 July 2012, ARR and KC collected a juvenile female *B. campbelli* (PSO-CZ 436; total length = 505 mm; SVL = 440 mm) on a tourist trail at Reserva Natural Río Ñambí (RNRÑ), municipality of Barbacoas, department of Nariño, Colombia (01.28592°N, 78.07433°W, datum WGS84; elev. 1431 m) that contained an adult male *Urotheca lateristriga* (Stained Lips Snake; PSO-CZ 437; total length = 430 mm; SVL = 300 mm; Fig. 1) in its stomach. The prey had been ingested tail first. The specimens are housed on Colección Zoológica Universidad de Nariño (PSO-CZ), Pasto, Nariño, Colombia.

Fig. 1. Juvenile *Bothrocophias campbelli* with stomach contents, an adult *Urotheca lateristriga*.

We thank H. García for assistance in the field, Fundación FELCA and their members M. F. Pai and C. F. Pai for permits and logistic help in the RNRÑ, and J. P. Hurtado for help with prey identification. PDAGC received Ph.D. funding from CAPES (bolsista da CAPES/CNPq – IEL Nacional - Brasil).

***COLUBER* (=*MASTICOPHIS*) *BILINEATUS* (Sonoran Whipsnake). DIET.** The diet of the diurnally active, swift-moving *Coluber bilineatus* includes lizards, birds, and occasionally small mammals, frogs, and snakes (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston Massachusetts. 336 pp.). On 25 July 2012 at 1320 h, while driving along the County Road south of Richards Road in southwestern New Mexico (31.6696°N, 108.8409°W; datum WGS 84) we encountered a DOR male *C. bilineatus* (total length = 1858 mm) that had recently ingested a *C. flagellum* (total length = 991 mm; Fig. 1). The *C. flagellum* had been ingested headfirst and completely consumed. This record is the first documentation of *C. flagellum* in the diet of *C. bilineatus*. The specimens (LACM 183338, 183339) and photo vouchers (LACM PC 1616, 1617) have been accessioned at the Natural History Museum of Los Angeles County, California.

BANASHEK**, Mojave Desert Rattlesnake Research, P.O. Box 235, Adelanto, California 92301, USA (e-mail: cssrattlesnake@yahoo.com); **JARRON J. LUCAS** and **AARON I. WELLS**, The Southwestern Herpetologists Society, San Gabriel Chapter, 1750 N. Altadena Dr., Pasadena, California 91107, USA.

Fig. 1. *Coluber bilineatus* found dead with a completely ingested *C. flagellum* protruding from its body, Hidalgo Co., New Mexico, USA.

***COLUBER* (=*MASTICOPHIS*) *BILINEATUS* (Sonoran Whipsnake). MAXIMUM LENGTH.** The maximum total length (TL) reported for *Coluber bilineatus* is ~1700 mm (Boundy 1995. Bull. Chicago Herpetol. Soc. 30:109–122). We captured and released a male *C. bilineatus* at ca. 1900 m elevation in the Peloncillo Mountains, Hidalgo Co., New Mexico, USA, that exceeds this length. Captured on 22 April 1995, at 1432 h, this snake measured precisely 1800 mm TL (SVL = 1265 mm) and weighed 460 g. We captured 15 *C. bilineatus* in the Peloncillo Mountains between 1995 and 2001. Males averaged 982 ± 70 (SE) mm SVL (N = 8, range 645–1265 mm). Females averaged 867 ± 48 mm SVL (N = 7, range 685–1076 mm).

A specimen collected from Portal, Cochise Co., Arizona, USA, and deposited in the American Museum of Natural History (AMNH 91620) measured 1331 mm SVL and 1486 mm TL but had an incomplete tail (measurements provided by D. Frost). Based on our small Peloncillo Mountains sample, where both males and females had mean tail/body length ratios of approximately 43% ($t = 2.23$, $df = 10$, $p = 0.43$), we calculate that AMNH 91620 would measure 1903 mm TL if the tail were complete.

BRYAN L. STARRETT, 1463 S Moonlight Dr., Tucson, Arizona 85748, USA (e-mail: Bvipers@aol.com); **ANDREW T. HOLYCROSS**, School of Life Sciences, Arizona State University, Tempe, Arizona 85287, USA (e-mail: andrewholycross@gmail.com).

***COLUBER* (=*MASTICOPHIS*) *BILINEATUS* (Sonoran Whipsnake). MORTALITY.** *Spermophilus variegatus* (Rock Squirrel) are known to aggressively attack snakes, often in defense of young (Haywood and Harris 1971. Texas J. Sci. 22:427; Knickerbocker 1988. Arizona Highways 64:12–15). Recently, Christman and Holycross (2001. Herpetol. Rev. 32:48) described an apparent attempt at predation by *S. variegatus* on *Lampropeltis pyromelana*.

On 23 June 1999, at 0826 h, one of us (LK) saw a *S. variegatus* at a rocky tinaja in the streambed of a densely wooded canyon in the Animas Mountains, Hidalgo Co., New Mexico, USA. Immediately after the squirrel was frightened off, a *Coluber bilineatus* (SVL ca. 1200 mm) was found writhing approximately 8 m from the point where the squirrel was first observed. The snake had sustained numerous puncture wounds to the head and anterior 1/3 of the body consistent with those that would be made by rodent incisors. The tail was missing from approximately 60 mm posterior of the vent. When approached, the snake struck haphazardly. Despite the injuries, the snake appeared to be in good condition.

Spermophilus variegatus occasionally take live vertebrate prey (Hoffmeister 1986. The Mammals of Arizona. Univ. Arizona Press, Tucson. 602 pp.) and may have been preying on the *C. bilineatus*. However, in our area most *S. variegatus* give birth in June (Ortega 1990. J. Mamm. 71:448–457), so the squirrel may have been defending itself or its young against a predatory attack by the snake.

LARRY KAMEES, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701-1201, USA (e-mail: lkkamees@email.uark.edu); **ANDREW T. HOLYCROSS**, Department of Biology, Arizona State University, Tempe, Arizona 85287-1501, USA.

***CROTALUS ATROX* (Western Diamondback Rattlesnake). DIET AND FEEDING BEHAVIOR.** *Crotalus atrox* are generalist predators that prefer a diet of small mammals, but are also known to consume birds, lizards and in some cases, insects (Klauber 1956. Rattlesnakes: Their Life, Habits, History and Influence on Mankind. Vol. 1. Univ. California Press, Berkeley. 708 pp.). Though the natural history and feeding ecology of *C. atrox* has been well documented in captivity, relatively few observations have been made in their natural environment. The feeding behavior of *Crotalus* spp. is generally characterized by a strike, envenomation, and release of the prey item. The snake later tracks the dead prey item for consumption. However, certain stimuli, such as small prey size and prey type, may influence the snake to hold prey after the strike (Kardong 1986. J. Comp. Psychol. 100:304–314). Here, I describe an in-situ observation of prey capture and consumption by a *C. atrox* in Taylor Co., Texas, USA. The observation documents a novel prey species for *C. atrox*, *Cophosaurus texanus texanus* (Texas Greater Earless Lizard), and is unusual in that the prey was not released after the strike.

FIG. 1. *Crotalus atrox* feeding on a *Cophosaurus texanus texanus* in Taylor Co., Texas, USA.

On 20 May 2010, at 1005 h, a *C. texanus* was observed running off the side of a dirt road at the Horse Hollow Wind Energy Center (32.25834°N, 100.02678°W; datum WGS84). While the lizard was running, it was struck and held by a *C. atrox* that was basking on a rock, initially undetected by both the prey and observer. The *C. texanus* was struck head-first, with the initial strike reaching just past the front legs of the lizard (Fig. 1). Consumption of the lizard began approximately 50 sec later and was completed in approximately 7 min.

I thank Caleb Gordon, Normandeau Associates, NextEra Energy, Inc., and Turner Biological Consulting for the opportunity to observe this event.

BRYAN SUSON, 680 Kathryn Ct., Green Oaks, Illinois 60048, USA; e-mail: bjsuson1@gmail.com.

***CROTALUS HORRIDUS* (Timber Rattlesnake). FUNGAL PATHOGENS.** Wildlife epidemiology has received a great deal of attention in recent years due in part to an increased awareness of disease prevalence and impacts on wildlife populations. Most notably, fungal species have been implicated in the decline, and even extinction, of anuran (Skerratt et al. 2007. EcoHealth 4:125–134) and bat (Blehert et al. 2009. Science 323:227) populations. More recently, fungal skin infections (and presumed fungal skin infections) have been implicated in the death of individual snakes (Allender et al. 2011. Emer. Infect. Dis. 17:2383–2284; Clark et al. 2010. Biol. Cons. 144:886–891), but little is known about the prevalence or virulence of these fungal pathogens in nature.

On 3 June 2012, two *C. horridus* (herein, "Snake A" and "Snake B") were collected from adjacent bluff prairies located on private property in Houston Co., Minnesota, USA, because of suspicious

FIG. 1. One of two *Crotalus horridus* collected during surveys in Houston County, Minnesota, USA, that tested positive for *Chrysosporium* sp.; note facial dermatitis circled in red.

looking facial dermatitis (Fig. 1). Both individuals were pre-ecdysis when found and were held for approximately five weeks before biopsy samples were sent for analysis; during this time they completed ecdysis. Small biopsies from the head of Snake A and body of Snake B, as well as shed skins from both animals, were sent to the US Geological Survey – National Wildlife Heath Center in Madison, Wisconsin for testing.

Tissue from the biopsies and affected areas of skin from the sheds were subjected to fungal culture at an incubation temperature of 24°C. Fungal isolates were examined microscopically for tentative identification. Most isolates were common environmental fungi that likely represented normal skin flora (e.g., *Aspergillus* and *Penicillium* spp.). However, two isolates (one from the biopsy of Snake A and one from the shed skin of Snake B) could not be identified by microscopic examination. A portion of the internal transcribed spacer region of the ribosomal RNA gene for both isolates was amplified and sequenced using universal primers. The sequences were identical to one another and >99.6% nucleotide match with *Chrysosporium ophiodiicola* (GenBank accession EU715819), a species isolated from a facial mass of a *Pantherophis alleghaniensis* (Eastern Ratsnake; Rajeev et al. 2009. J. Clin. Microbiol. 47:1264–1268). However, further analyses are necessary to determine whether the isolates from the *C. horridus* represent the same species as that from the *P. alleghaniensis*. Histopathology was performed on a small portion of the skin from one of the biopsies using special stains for fungi. No fungal elements were observed, but the sample was taken from the edge of the biopsy and likely did not contain the actual lesion; histopathology could not be performed on the remaining biopsy as that sample was used for culture analysis.

This is the first documented occurrence of a *Chrysosporium* sp. on free-ranging wild snakes in Minnesota; while mortality has been associated with *Chrysosporium* fungi elsewhere (Allender et al. 2011, *op. cit.*; Rajeev et al. 2009, *op. cit.*), it is not known whether this *Chrysosporium* sp. is impacting snake survival in Minnesota. Rajeev et al. (2009) reported that the infected *P. alleghaniensis* died in captivity two months after surgically removing the lesions; similarly, Allender et al. (2011) noted that all three of the *Sistrurus catenatus catenatus* (Eastern (Massasauga Rattlesnakes) with *Chrysosporium* infections from Illinois died in captivity within three weeks after discovery. However, both of the Minnesota animals have improved over the course of 10 weeks in captivity without a specific course of treatment; Snake B now appears asymptomatic.

We thank Erica Hoaglund and Dan Lais for reviewing this note. We also thank Marc Bailey, Dv Kaufman, Dan Keyler, Jeffrey B. LeClere, Brian Potter, and Eric Thiss for their assistance in the field and Kevin McCurley for bringing this issue to our attention and providing technical guidance in the field. A special thank you goes to Tom Taggert and Valley Veterinary Clinic for voluntarily collecting biopsies from both snakes. We would also like to thank the USGS National Wildlife Heath Center in Madison, Wisconsin for testing samples and Carol U. Meteyer for examining the histopathology.

CHRISTOPHER E. LORCH**, University of Wisconsin-Madison, Molecular and Environmental Toxicology Center, 1300 University Avenue, Madison, Wisconsin 53706, USA (e-mail: jmlorch@wisc.edu).

***CROTALUS HORRIDUS* (Timber Rattlesnake). REPRODUCTION.** *Crotalus horridus* is a widely distributed species native to the eastern United States; however, most research has focused on northern populations. In Georgia, *C. horridus* typically mates from August to October and gives birth from mid-August to mid-September. However, there have been reports of snakes at higher elevations delaying birth until early October (Jensen et al. 2008. The Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens. 575 pp.). On 19 October 2011, we collected a road killed female C. *horridus* with a distended lower body in Baker Co., Georgia, USA. No body size measurements were taken on the specimen due to its advanced state of decomposition. Upon dissection, we observed between 8–12 fetuses (SVL range = 291–330 mm) in the latter stages of development. This observation is evidence of late season pregnancy in *C. horridus* in the southeastern Coastal Plain.

THOMAS D. BALDVINS (e-mail: tom.baldvins@vikings.berry.edu), **CHARLES M. OLIVER** (e-mail: coliver@jonesctr.org), **JENNIFER M. HOWZE** (e-mail: jhowze@jonesctr.org), and **LORA L. SMITH** (e-mail: lsmith@jonesctr.org), Joseph W. Jones Ecological Research Center, 3988 Jones Center, Newton, Georgia 39870, USA.

***CROTALUS VIRIDIS* (Prairie Rattlesnake). DIET.** *Crotalus viridis* feeds on small mammals (mice, ground squirrels, rats, small rabbits); it will also consume lizards, amphibians, and other snakes. On 3 July 2012, an adult *C. viridis* was photographed attempting

FIG. 1. Adult *Crotalus viridis* attempting to consume an adult male *Falco sparverius*.

to consume a still quivering adult male *Falco sparverius* (American Kestrel) at the Chihuahuan Desert Rangeland Research Center, Summerford Mountain (32.532536°N, 106.790825°W; datum WGS84), New Mexico, USA (Fig. 1). On 06 July 2012, the site was revisited and the kestrel was found, apparently regurgitated, after being swallowed down to the top of the wings. To our knowledge, this represents the first case of attempted predation on *F. sparverius* by *C. viridis*.

ROXANNE M. CHEPSONGOL and **DOUGLAS W. BURKETT**, P.O. Box 30003 MSC 3 JER, Las Cruces, New Mexico 88003, USA.

***CROTALUS VIRIDIS* (Prairie Rattlesnake). REPRODUCTION/COMBAT.** Male-male combat behavior is a component of the reproductive cycle of pitvipers (Aldridge and Duvall 2002. Herpetol. Monogr. 16:1–25). The occurrence of male-male combat behavior is reported in North America during spring (Gloyd 1947. Nat. Hist. Misc. 12:1–4) and summer (Klauber 1972. Rattlesnakes: Their Habits, Life History, and Influence on Mankind, 2nd ed. Univ. California Press, Berkeley; Holycross 1995. Herpetol. Rev. 26:37–38). Here we report field observations of two combat episodes between *C. viridis* in early autumn and spring in northern Chihuahua, Mexico.

At 1130 h on 23 September 2008, 1 km W of the gap that leads to "El Vergel," at km 304 of the Ciudad Juarez–Chihuahua Federal Highway 45, municipality of Juárez, Chihuahua, Mexico (31.20223889°N, 106.51834444°W, datum WGS84; elev. 1285 m) one of us (EMR) encountered two male *C. viridis* (ca.1100 mm SVL) engaged in combat (Fig. 1). The observation occurred in dune habitat with vegetation composed primarily of *Prosopis glandulosa* and *Gutierrezia sarothrae*, about 20 m away from the location of a female *C. viridis* and her newborn offspring. Combat continued for ca. 10 min, after which the defeated male withdrew. A film and photos of the combat are deposited in the scientific collection of vertebrates of the Autonomous University of Juárez UACJ (CHI-VER-189-08-06). The second combat event took place on 15 April 2003, at 1100 h, on the campus of the Autonomous University of Juárez (UACJ) (31.49132095°N, 106.41687207°W; datum WGS84). These observations are unusual in that they occurred outside of the typical summer breeding season of the species.

***DIPSAS ALTERNANS* (Jan's Snail-Eater, Dormideira). DEFENSIVE BEHAVIOR.** The genus *Dipsas* comprises small and nonvenomous Neotropical snakes that show several defensive strategies, some of which are thought to mimic venomous snakes of the genus *Bothrops* (Sazima 1992. *In* Campbell and Brodie Jr. [eds.], Biology of Pitvipers, pp. 199–216. Selva, Tyler, Texas). Recently, Maia-Carneiro et al. (2012. Biotemas 25:207–210) described three defensive behaviors in *Dipsas alternans*: immobility, spherical body coiling, and hiding the head among the body coils. In our long-term studies of snakes in the Atlantic forest region of the state of Paraná, southern Brazil, we have collected seven *D. alternans*. Five of these demonstrated the same defensive behaviors described by Maia-Carneiro et al. (*op. cit.*), but two exhibited a unique defensive behavior: spiral coiling. The two snakes were found moving within the leaf-litter on the ground of the forest. Both stayed immobile, but after manipulation, rolled their body into a perfect plain spiral, with their heads completely visible in the center (Fig. 1), displaying three spots on the dorsum of the head, as described by Maia-Carneiro et al. (*op. cit.*). In captivity, the specimens never showed any other defensive behaviors, but always forming the spiral when stimulated. Although the exact function of this behavior remains unknown, the spiral shape might confuse a potential predator or mimic the spiral-shaped dead leaves of common tree fern in the area, *Dicksonia sellowiana* (Cyatheaceae). The specimens are deposited in the herpetological collection of the Museu de História Natural Capão da Imbuia (MHNCI.691, Camarinhos, municipality of Campo Largo, Paraná; 25.43°S, 49.63°W, datum WGS 84; MHNCI.3005, Rio do Meio, municipality of Antonina, Paraná; 25.33°S, 48.75°W, datum WGS 84).

We thank Pricila Fogaça for the revision on the English version of the manuscript, and John Willson for additional suggestions.

***EPICTIA TENELLUS* (Guyana Blind Snake). PREDATION.** The vast majority of anurans, especially mid-sized and small species, feed on arthropods and other invertebrates (Duellman and 1994. Biology of Amphibians, 2nd ed. Johns Hopkins Univ. Press, Baltimore. 670 pp.). However, there are a few field observations of snake predation by frogs. *Leptodactylus labyrinthicus* (Pepper Frog) have been recorded to prey on several snake species: *Sibynomorphus neuwiedi, Trilepida koppesi,* and *Typhlops brongersmianus* (Fonseca et al. 2012. Herpetol. Notes 5:167–168; Vaz-Silva et al. 2003. Herpetol. Rev. 34:359). During necropsy of 74 *L. labyrinthicus,* deposited in Zoological Collection of the Universidade Federal do Mato Grosso, we found an adult *Epictia tenellus* (SVL = 156 mm; total length = 172 mm) in the large intestine of a male frog (SVL = 151 mm) from Mato Grosso State, Brazil. The fact that only one snake was recorded suggests that this frog is an opportunist feeder that infrequently feeds on uncommon snakes such as *E. tenellus*.

MAYSA H. R. TOLEDO (e-mail: maysa_hrtoledo@hotmail.com) and **DRAUSIO H. MORAIS**, UNESP, Universidade Estadual Paulista, Campus Botucatu, Instituto de Biociências, Departamento de Parasitologia, Botucatu, São Paulo, Brazil.

***FICIMIA STRECKERI* (Tamaulipan Hook-nosed Snake). REPRODUCTION.** *Ficimia streckeri* is distributed in extreme southern Texas, USA, and Mexico from Nuevo León, Tamaulipas, and San Luis Potosi to the central Mexican Plateau, Hidalgo and north of Veracruz (Wright and Wright. 1957. Handbook of Snakes of United States and Canada. Vol. 1. Cornell Univ. Press, Ithaca, New York. 564 pp.). It inhabits thorn forest, tropical deciduous forest, and cloud forest (Hardy 1976. Cat. Amer. Amphib. Rept. 181.1–181.2). It is seldom seen and little is known about its natural history, including reproduction (Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. 430 pp.). On 1 April 2012, at 1848 h, in tropical forest of the Plan de Zapotal, municipality of Pisaflores (21.1800.820°N, 98.5746.858°W, datum WGS 84; elev. 495 m), Hidalgo, Mexico, we found an adult female *F. streckeri* (CIB-4290; SVL = 323 mm; tail length = 51 mm). The female was gravid, with three eggs (mean volume ± SE = 537.4 ± 27.6 mm^3; mass = 0.962 ± 0.032 g), and also contained eight non-vitellogenic follicles, which might be indicative of laying multiple clutches annually. These data represent a useful contribution to our limited knowledge of the natural history of this species. We thank the projects CONABIO FB1580/JM001/12, and FOMIX 2012/191908.

FIG. 1. Prey items (*Ocypode* sp. and *Cerithidea* sp.) regurgitated by *Fordonia leucobalia* from Sonadia Island, Bangladesh.

***FORDONIA LEUCOBALIA* (Crab-eating Snake). DIET.** *Fordonia leucobalia* is a medium-sized, rear fanged, aquatic snake found in the tidal rivers and mangrove habitats from Southeast Asia to northern Australia (Das 2010. Reptiles of Southeast Asia. New Holland Publishers Ltd. UK. 376 pp.). *Fordonia leucobalia* is known as a crustacean eater, primarily feeding on hard-shelled crabs of the families Grapsidae and Ocypodidae, and on mud lobster (*Thalassina anomala*; Voris and Murphy 2002. J. Nat. Hist. 36:1621–1632; Karns et al. 2002. Raffles Bull. Zool. 50:487–498). Herein, we report the first observation of *F. leucobalia* feeding on a gastropod.

We conducted a field survey of homalopsid snakes in the intertidal zone of Sonadia Island, Bangladesh, from 9 to 17 July 2012. Sonadia Island is a roughly 4900-ha barrier island located in the far southeastern corner of Bangladesh, northwest of Cox's Bazaar town. The island supports some of the last remaining patches of natural mangrove forest found in southeastern Bangladesh. On 15 July 2012, we found eight *F. leucobalia* in the early succession mangrove forest, in the landward side of the intertidal zone. Upon capture, one *F. leucobalia* (adult male; SVL = 52.8 cm, tail length = 7.8 cm, 92 g) defecated a *Cerithidea* sp. (Fig. 1; total length = 1.5 cm; 3 g). *Cerithidea* sp. is small, hard-shelled gastropod, abundant in the mudflats and mangrove forest in this region (Siddiqui et al. 2007. Encyclopedia of Flora and Fauna of Bangladesh: Volume 17: Molluscs. Asiatic Society of Bangladesh, Dhaka, Bangladesh. 415 pp.). Feeding on gastropods has not been previously recorded for any homalopsid snakes. Silva et al. (2011. Herpetol. Notes 4:373–375) recently reported an observation of a sea snake (*Lapemis curtus*) feeding on a gastropod in Sri Lanka, indicating that feeding on gastropods by aquatic snakes (homalopsid snakes and sea snakes) might be more common in this region than anticipated.

SHAHRIAR CAESAR RAHMAN, Department of Environmental Science, Independent University, Bangladesh (e-mail: caesar_rahman2004@yahoo.com); **A. H. M. ALI REZA**, Division of Biological and Physical Sciences, Delta State University, Cleveland, Mississippi 38733, USA (e-mail: areza@deltastate.edu).

***HELICOPS ANGULATUS* (Watersnake). DIET.** *Helicops angulatus* occurs in northern South America, with records from Atlantic forest or Amazonian environments in Colombia, Venezuela, Trinidad, Guiana, Suriname, French Guiana, Ecuador, Peru, Bolivia, and northern and northeastern regions of Brazil (França et al. 2006. Occ. Pap. Sam Noble Oklahoma Mus. Nat. Hist. 17:1–3; Infante-Rivero et al. 2008. Herpetotropicos 4:39–39). They are

aquatic, nocturnal, and feed on fish, tadpoles, and occasionally adult anurans (Ford et al. 2002. Carib. J. Sci. 38:129–132; Scartozzoni 2009. Unpubl. DS thesis. Universidade de São Paulo, São Paulo).

A mature female *H. angulatus* (SVL = 297 mm) was captured on 9 November 2010, at 2200 h, on the edge of a stream in Atlantic Forest of Cruz do Espírito Santo municipality, Paraíba State, northeastern Brazil. Dissection revealed remains of an adult *Leptodactylus natalensis* (SVL = 49.4 mm) in the snake's stomach. This is the first record of consumption of *L. natalensis* by *H. angulatus*. Because both species are sympatric and their habitats are similar, this type of interaction may be expected. The habit of making nests and vocalizing at the edge of slow-flowing streams (Amorim et al. 2009. Pap. Avul. Zool. 49:1–7) may make *L. natalensis* more vulnerable to predators such as *H. angulatus* during the breeding season. The snake and frog are housed in the Coleção Herpetológica da Universidade Federal da Paraíba, João Pessoa (CHUFPB 00005).

We thank the Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renováveis (IBAMA) for permits. DJS would like to thank CAPES for their current Ph.D. scholarships, CAPES for scholarship to ASP and RR, and CNPq for scholarship to RLA and research fellowship to DOM. FGRF thanks the financial support from the CNPq (Universal grant 474250/2010-5). DOM thanks the financial support from the CNPq (Universal grant 481537/2009-0).

***LAMPROPELTIS CALLIGASTER CALLIGASTER* (Prairie Kingsnake). ANTHROPOGENIC MORTALITY.** As a component of a *Geomys breviceps* (Baird's Pocket Gopher) study 6 km E Spearsville, Union Parish, Louisiana, USA, metal kill traps (Trapline Products, Menlo Park, California, USA), which constrict the abdomen and humanely euthanize the gopher, were set in open pocket gopher burrows in evenings and left overnight. On 30 April 2011, I found an adult female (SVL = 980 mm) *Lampropeltis calligaster calligaster* that had entered an open pocket gopher burrow and been killed in the trap. It appeared that the snake had entered the burrow at the site of excavation. The specimen was subsequently deposited in the Henderson State University Collection of Herpetology (HSU 1641). To my knowledge, this is the first report of a snake dying as a result of a pocket gopher kill trap. Active pocket gopher burrows are typically closed off to the surface except for short durations of burrow maintenance. When open, however, these burrows may provide *L. calligaster calligaster* with refugia and/or pocket gophers, which are known prey of the snake (Connior et al. 2009. Herpetol. Rev. 40:98; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, D.C. 668 pp.).

MATTHEW B. CONNIOR, Health and Natural Sciences, South Arkansas Community College, El Dorado, Arkansas 71730, USA; e-mail: mconnior@southark.edu.

***LAMPROPELTIS NIGRA* (Black Kingsnake). DIET.** The diet of *Lampropeltis nigra* (taxonomy follows Pyron and Burbrink 2009. Zootaxa 2241:22–32) is diverse and includes a variety of lizard eggs, turtle eggs, snakes and their eggs, mammals, and birds (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, D.C. 680 pp.; Green and Cobb 2011. Herpetol. Rev. 42:615). On 15 June 2010, we captured a male *L. nigra* (SVL = 104.2 cm; total length = 118.4 cm; 380 g) in a trap array located on the Camp Shelby Joint Force Training Center, De Soto National Forest, Perry County, Mississippi, USA. During transportation, the *L. nigra* regurgitated a juvenile *Cemophora coccinea* (Scarletsnake), an *Agkistrodon* sp., and *Crotalus adamanteus* (Eastern Diamond-backed Rattlesnake) rattle segments. Rattle segments were identified as *C. adamanteus* due to the absence of *C. horridus* from the study area (Lee 2009. Southeast. Nat. 8:639–652) and the segments were too large to be those of *S. miliarius*. To the best of our knowledge this is the first documented occurrence of *C. coccinea* in the diet of *L. nigra*, and represents a novel food item for the genus *Lampropeltis* (Ernst and Ernst 2003, *op. cit.*).

DONALD J. NEWMAN III (e-mail: DNewman@TNC.org) and **JAMES R. LEE** (e-mail: JLee@TNC.org), The Nature Conservancy, Camp Shelby Joint Forces Training Center, CSJFTC-ENV Building 6530, Camp Shelby, Mississippi 39407, USA.

***LAMPROPELTIS SPLENDIDA* (Desert Kingsnake). DIET.** *Lampropeltis splendida* is a common Chihuahuan Desert species reported to feed on a variety of prey, including bird eggs and hatchlings (Degenhardt et al. 1996. The Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, New Mexico. 431 pp.). Avian nest predation by snakes has been reported infrequently, but may account for as much as 90% of all nest predation (Weatherhead and Blouin-Demers 2004. J. Avian Biol. 35:185–190). On 20 July 2012, at 0140 h, we recorded a *L. splendida* predating an *Empidonax traillii extimus* (Southwestern Willow Flycatcher) nest with three nestlings (Fig. 1). The nest was located 1.5 m above the ground in a live 4.5-m tall *Salix exigua* (Coyote Willow). The locality was near San Marcial, Socorro Co., New Mexico, USA. A photo series from a trail camera with infrared capabilities documented four minutes of activity, although it is likely the predation event lasted much longer. To our knowledge, this is the first report of a Southwestern Willow Flycatcher

FIG. 1. *Lampropeltis splendida* predating an *Empidonax trailii extimus* nest including three nestlings in a *Salix exigua* dominated riparian area near San Marcian, Socorro Co., New Mexico, USA.

nest predation by *L. splendida*, although there are several records of Willow Flycatcher nest predation by *L. californiae* (Smith et al. 2002. Nongame and Endangered Wildlife Program Technical Report 191. Arizona Game and Fish Dept., Phoenix, Arizona).

We thank Charles W. Painter for reviewing this note. Research was conducted under United States Fish and Wildlife Service Permit TE819475-2.

SHAUN T. ROOT (e-mail: sroot@usbr.gov) and **DARRELL AHLERS** (e-mail: DAhlers@usbr.gov), Bureau of Reclamation, Fisheries and Wildlife Group, PO Box 25007, Denver, Colorado 80225, USA.

***LEPTODEIRA ANNULATA* (Banded cat-eyed Snake). DIET.** *Leptodeira annulata* has a wide distribution in Mexico, Central, and South America (Peters and Orejas-Miranda 1986. Catalogue of the Neotropical Squamata: Part I, Snakes. Revised ed. Smithsonian Institution, Washington D.C. 347 pp.). This snake has arboreal habits, but can also be found on the ground and in water (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150; Ávila and Morais 2007. Herpetol. Rev. 38:278–280). Its diet is composed mainly of small frogs (Vitt 1996. Herpetol. Nat. Hist. 4:69–76). Here we report a field observation of attempted predation upon a large-bodied anuran by an adult *L. annulata* in the Brazilian Caatinga.

At 1810 h on 25 October 2009 in the Fazenda Tanques, municipality of Santa Maria, state of Rio Grande do Norte, Brazil (05.87°S, 35.70°W, datum WGS84; elev. 137 m), we found an adult female *L. annulata* (SVL = 602 mm) in herbaceous vegetation on the border of a pond, biting the right hind limb of an adult *Leptodactylus* cf. *macrosternum*. The anuran continuously emitted open-mouthed distress calls (Fig. 1), and tried to escape from the snake. The *L. annulata* held the frog for approximately 15 min while anchoring its body by wrapping its caudal region around vegetation, but eventually the frog was able to escape.

Although we recognize that our presence may have disturbed the snake, the failed predation attempt may have occurred due to the large size and great vitality of the frog. Despite the batrachophagic habits of *L. annulata*, ingestion of large anurans does not seem to be common in this species. In an analysis of 66 specimens of *L. annulata* from the Brazilian Amazon, Vitt (*op. cit.*) reported only small frogs, with mean prey length (29.9 ± 3.9 mm) and width (11.0 ± 1.4 mm) much smaller than the *L.* cf. *macrosternum* we observed (estimated body length = 80 mm; body width = 39 mm).

The *L. annulata* (CHBEZ 2631) was vouchered in the herpetological collection of the Universidade Federal do Rio Grande do Norte, Natal, Brazil. This study was supported by research grants from the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) to JSJ (process 107757/2010-9) and EMXF (process 309424/2011-9), and from the Coordernação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) to RFDS.

FIG. 1. Attempted predation by *Leptodeira annulata* on *Leptodactylus cf. macrosternum* in the Brazilian Caatinga.

***MONTATHERIS HINDII* (Kenya Montane Viper). DIET.** *Montatheris hindii* is a small Kenyan viperid endemic to high altitude moorlands of the Aberdare Mountains and Mt. Kenya. Little is known about the natural history of this species although its diet consists of lizards and frogs, while small rodents have been suggested as prey (Spawls et al. 2004. A Field Guide to the Reptiles of East Africa. A & C Publishers Ltd., London. 543 pp.).

On 4 October 2011, during a small mammal survey in the Eastern Province of Kenya, Meru South District, Mt. Kenya National Reserve (00.16392°N, 37.44714°E, datum WGS 84; elev. 2980 m) an adult male *M. hindii* (total length = 299 mm; 16 g) was captured in a pitfall trap line. The pitfall line was situated in a transitional region between the upper montane forest zone and the Ericaceous zone along the eastern slope of Mt. Kenya. Vegetation in the immediate vicinity of the pitfall included tussock-forming grasses and herbaceous plants 0.5–1 m in height and this alpine grassland was bordered by a grove of *Hagenia abyssinica* trees ca. 100 m distant. While in the bucket trap, the snake had killed and half-consumed a *Sylvisorex granti mundus* (5.0 g; Fig. 1). The *M. hindii* was deposited at the National Museum of Kenya, Mammalogy Section (TCD 3374) and the *S. granti mundus* is a voucher at the Field Museum of Natural History - Chicago (FMNH 216941). This is the first record of *S. granti mundus* in the diet of *M. hindii*. However, because the event occurred in a pitfall trap, the importance of this species as prey for *M. hindii* remains unknown.

TERRENCE C. DEMOS, Department of Biology, The Graduate Center – CUNY, 365 Fifth Avenue, New York, New York 10016, USA and Mammals Division, Field Museum of Natural History, 1400 S. Lake Shore Dr., Chicago, Illinois 60605, USA (e-mail: terrencedemos@gmail.com); **BERNARD**

FIG. 1. A *Montatheris hindii* consuming a *Sylvisorex granti mundus* in a pitfall trap in Mt. Kenya National Reserve, Kenya.

AGWANDA, Mammalogy Section, National Museums of Kenya, P.O. Box 40658, Nairobi, Kenya (e-mail: ben_risky@yahoo.co.uk); **EDWARD A. MYERS**, Department of Biology, College of Staten Island, 2800 Victory Blvd. 6S-143, Staten Island, New York 10314, USA and The Graduate Center – CUNY, 365 Fifth Avenue, New York, New York 10016, USA (e-mail: emyers@gc.cuny.edu).

***NERODIA FLORIDANA* (Florida Green Watersnake). DIET.** Although no diet studies have been completed (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. Univ. Oklahoma Press, Norman. 496 pp.), *Nerodia floridana* eat a wide variety of aquatic prey (Holbrook 2012. A Field Guide to the Snakes of Southern Florida. ECO Publ., Rodeo, New Mexico. 225 pp.). Though invasive species have the potential to cause harm to some species, there are cases where invasive fish have outcompeted native fish, increasing prey availability and ultimately benefiting watersnakes (*Nerodia* spp.) (King et al. 2006. Can. J. Zool. 84:108–115). During aquatic trapping efforts by the Center for Snake Conservation on 19 March 2012 in a tributary of Fisheating Creek, Glades Co., Florida, USA (26.909461°N, 81.329154°W; datum WGS84), a *N. floridana* (SVL = 595 mm) was accidentally drowned in an aquatic minnow trap. The snake contained a recently ingested *Hoplosternum littorale* (Brown Hoplo Catfish; total length = 110 mm). This is the first record of the native *N. floridana* feeding on this common nonnative species; however, it should be noted that several large *N. floridana* were encountered in the area, which supports dense populations of *H. littorale* (Center for Snake Conservation, unpubl. data). Both snake and fish were deposited together (FLMNH 166557) in the Florida Museum of Natural History Reptile and Amphibian (Herpetology) Collection.

YOUNG** (e-mail: cayoung@snakeconservation.org), **DAVID P. YOUNG, JR.** (e-mail: dyoung@snakeconservation.org), Center For Snake Conservation, 1581 Ridgeview Drive, Louisville, Colorado 80027, USA; **NOAH GREENWALD**, Center for Biological Diversity, P.O. Box 11374, Portland, Oregon 97211, USA (e-mail: ngreenwald@biologicaldiversity.org).

***PANTHEROPHIS OBSOLETUS* (Texas Ratsnake). DIET AND FEEDING BEHAVIOR.** *Pantherophis* spp. are a frequently documented predator of bird nests (Weatherhead and Blouin-Demers 2004. J. Avian Biol. 35:185–190) and are known to frequently use arboreal habitats (Mullin et al. 2000 Herpetol. Rev. 31:20–22). During a study of nest predation in Mississippi Kites (*Ictinia mississippiensis*) in White River National Wildlife Refuge, Arkansas, USA, we documented, using time-lapse video, the simultaneous visit of an active kite nest, 24.8 m high, by two *P. obsoletus*. At 1610 h (CST) on 13 June 2009, a single *P. obsoletus* entered the nest, struck the brooding adult, which flew from the nest, and immediately began consuming one of the two nestlings. While the snake tried to swallow the nestling, it was pulled out of the nest by an adult kite. Later that night (2107 h), a single *P. obsoletus* entered the same nest, again flushing the brooding adult, and immediately bit and coiled around the remaining nestling, which it swallowed within minutes. Following the consumption of the chick, this snake continued searching the nest for additional prey. At this point (2129 h), a second *P. obsoletus* entered the nest and began searching the nest in a similar manner. Both snakes continued searching the nest until 2206 h, when both departed. We do not know if either snake in the nest at 2129 was the same individual pulled out of the nest earlier in the day.

Since 2005, studies in Arkansas have documented *P. obsoletus* consuming both eggs and nestlings of Mississippi Kites (Bader and Bednarz 2009. Wetlands 29:598–606), which represented a previously unrecorded prey item. Additionally, whereas simultaneous visits by *P. alleghaniensis* and *P. obsoletus* have been observed at nests close to ground level (Carter et al. 2007. J. Field Ornithol. 78:390–394; Kukal and Cox 2010. Herpetol. Rev. 41:371–372), to our knowledge our observation is the first to document such an event in the forest canopy. The context of this event generates questions related to the mechanisms used by *Pantherophis* to locate nests as well as the frequency and significance of such social interactions during foraging. As the use of video systems to study nest predation in birds increases (Cox et al. 2012. Stud. Avian Biol. 43:185–210), researchers may discover that social interactions during foraging are more common among snakes than previously known.

SCOTT J. CHIAVACCI (e-mail: schiavacci@gmail.com) and **JAMES C. BEDNARZ** (e-mail: jim.c.bednarz@gmail.com), Arkansas State University, PO Box 599, Jonesboro, Arkansas 72401, USA.

***PANTHEROPHIS VULPINUS* (Western Fox Snake). PREDATION.** American Badgers (*Taxidea taxus*) are opportunistic feeders, and their diets include a number of small mammal species, a variety of reptiles, amphibians, birds, insects, and even fish (Hoodicoff 2003. Ecology of the Badger (*Taxidea taxus jeffersonii*) in the Thompson Region of British Columbia: Implications for Conservation. Univ. of Victoria, British Columbia. 126 pp.). On 7 July 2011, a *T. taxus* was observed depredating a nest of reptile eggs on Squaw Creek National Wildlife Refuge, Missouri, USA. The nest was located on the bank of a drainage ditch (40.1099°N, 95.2434°W; datum NAD83). Upon close inspection of the area after the badger retreated, several other excavated nest holes were located in the immediate vicinity. In total there were 220 exposed snake eggs and nine turtle eggs. Over 97% of the eggs had been depredated or were in poor (severely dented or smashed) condition. Six eggs were in moderate to good condition and were kept for incubation. All six eggs hatched and were identified as *Pantherophis vulpinus*. This represents the first known record of predation on *P. vulpinus* eggs by *T. taxus*.

We thank Mark Mills, Missouri Western State University, for assistance identifying the snakes. The findings and conclusions in this article are those of the author(s) and do not necessarily represent the views of the U.S. Fish and Wildlife Service.

JACKIE L. DAVIS (e-mail: jld24120@ucmo.edu) and **DARRIN M. WELCHERT**, U.S. Fish and Wildlife Service, Squaw Creek N.W.R., PO Box 158, Mound City, Missouri 64470-0158, USA.

***PHILODRYAS NATTERERI* (Paraguay Green Racer). DIET.** *Philodryas nattereri* is a diurnal snake belonging to the family Dipsadidae and is widely distributed in the semiarid regions of Brazil. The diet of this species consists mainly of lizards, amphibians, birds, and small mammals (Vitt 1980. Pap. Avul. Zool. 34:87–98). Here we report the first documented predation of *Leptodactylus vastus* (Northeastern Pepper Frog) by *P. nattereri* and the encounter of a theraphosid spider in the snake's stomach contents.

An adult male *P. nattereri* (SVL = 845 mm) was collected alive in the Mocambinho community, City of Nossa Senhora de Nazaré, Piauí, Brazil (04.632667°S, 42.244694°W, datum SAD 69; elev. 117 m), on 04 July 2012 at 1630 h. During transport, the animal regurgitated its stomach contents, including a *L. vastus* and part of a theraphosid spider. We could not identify the species of spider because of its advanced digestion. We believe that the spider was preyed upon by the frog and some parts of the exoskeleton were released into the snake's stomach. The snake and stomach contents were deposited in the Coleção Zoológica Delta do Parnaíba (CZDP 0550) of Universidade Federal do Piauí-UFPI.

We thank Anderson Guzzi and Mirco Solé for suggestions and English revision, João Paulo Vasconcellos for the help during the fieldwork, and Instituto Brasileiro do Meio Ambiente e Recursos Naturais (IBAMA) for permits (number: 30174-1).

***PITUOPHIS CATENIFER* (Gophersnake). DIET.** Of 2600 *Pituophis catenifer* specimens examined by Rodriguez-Robles (2002. Biol. J. Linn. Soc. 2002:165–183), 213 contained birds or their eggs. We herein provide the first verified report of *P. catenifer* preying on *Lanius ludovicianus* (Loggerhead Shrike) nestlings and eggs.

During a 2012 *L. ludovicianus* study we used remote-triggered wildlife cameras to monitor nests in southeastern New Mexico (Chaves, Eddy, and Lea counties). On 29 April 2012 a ca. 1.4 m (total length) *P. catenifer* was photographed at a nest located 1.7 m off the ground and initially containing six nestlings that were within a week of fledging (Fig. 1). The *P. catenifer* preyed on a nestling at ~2150 h and another at 2203 h. On 30 April 2012, a ca. 0.9 m (total length) *P. catenifer* was photographed eating *L. ludovicianus* eggs at 1345 h while being mobbed by both adult shrikes. The nest was located in a *Prosopis glandulosa* (mesquite tree) 1.1 m off the ground. The *P. catenifer* left after eating at least one egg; the female shrike continued incubation of the nest for the remainder of that day, according to subsequent images. The nest was empty the following day, suggesting that the *P. catenifer* may have returned during the night of 30 April 2012 (the camera on this nest was not capable of infrared nighttime photography).

FIG. 1. A *Pituophis catenifer* preying on a nestling *Lanius ludovicianus* in New Mexico.

This work was funded by the Dunes Sagebrush Lizard/Lesser Prairie Chicken Candidate Conservation Agreement (CCA) Research Fund and administered by the Center of Excellence for Hazardous Materials Management (CEHMM, Carlsbad, New Mexico). ***SISTRURUS CATENATUS CATENATUS* (Eastern Massasauga). DIET.** On 23 July 2012, at 2233 h, an adult female *Sistrurus catenatus catenatus* (SVL = 61 cm) was found on a road in the Magnetawan First Nation, Ontario, Canada, after being struck and killed by a vehicle. The snake had several feathers protruding anterior to the cloaca and a necropsy revealed two outer remiges (primary flight feathers) and several down feathers in the posterior portion of the gastrointestinal tract. In light of the time of year, location and surrounding habitat, coloration and vane width of the feathers, the bird was identified as a female Red-winged Blackbird (*Agelaius phoeniceus*). Based on the lengths of the two outer remiges (64.3 and 65.8 mm), we concluded that the bird was an adult female (average remige length for adult female *A. phoeniceus* is 67.0 mm, whereas average remige length for fledglings is 44.5 mm; Holcomb and Twiest 1968. Ohio J. Sci. 68:277–284).

Overall, *S. c. catenatus* is thought to be an ambush predator that preys upon small animals found within its wet habitat (swamps, marshes, bogs, fens, floodplains, and woods). The diet of adults predominately consists of small mammals (shrews, voles, and mice), but they are also known to consume crayfish, centipedes, insects, fish, amphibians, lizards, snakes, birds, and carrion (Ditmars 1908. The Reptile Book. Doubleday, Page and Company, New York. 472 pp; Ernst and Ernst 2011. Venomous Reptiles of the United States, Canada and Northern Mexico. John Hopkins Univ. Press, Baltimore, Maryland. 352 pp.; Rubio 2010. Rattlesnakes of the United States and Canada. ECO Herpetological Publishing & Distribution, Rodeo, New Mexico. 307 pp.). *Agelaius phoeniceus* are common in wet, marshy areas but may rarely be encountered by an ambush predator like *S. c. catenatus*. Keenlyne and Beer (1973. J. Herpetol. 7:383–384) found that a *S. c. catenatus* in Wisconsin fed upon a fledgling *A. phoeniceus*; however, the fledgling blackbird was only one of 91 food items found. Our observation represents the first record of *S. c. catenatus* feeding on an adult *A. phoeniceus*.

We thank Chris Blomme and the Laurentian University Vertebrate Museum for their consultation and insight. Jenn Baxter-Gilbert, Sean Boyle, Ron Maleau, and Chris Neufeld assisted in the field. Financial support was provided by Magnetawan First Nation, Laurentian University, the Ontario Ministry of Natural

Resources, and the Ontario Ministry of Transportation. All research was conducted under an approved Laurentian University Animal Care Committee protocol, and authorized by Magnetawan First Nation's Chief and Band Council and the Ontario Ministry of Natural Resources.

***STORERIA DEKAYI* (Dekay's Brownsnake). DIET.** *Storeria dekayi* is a small natricine snake of the eastern United States that feeds primarily on slugs and earthworms. Slug species reported to have been consumed by *S. dekayi* include *Arion hortensis*, *Deroceras laeve*, and *D. reticulatum* (Judd 1954. Copeia 1954:62–64; Fitch 1999. A Kansas Snake Community: Composition and Changes over 50 Years. Krieger Publ. Co., Malabar, Florida. 165 pp.); earthworms have not been identified to either genus or species. In addition to its preferred prey, *S. dekayi* has also been reported to consume snails, insects, isopods, mites, spiders, small fish, and amphibians (Judd, *op. cit.*; Wright and Wright 1957. Handbook of Snakes of the United States and Canada, Vol. 2. Cornell Univ. Press, Ithaca, New York. 441 pp; Langlois 1964. Ohio J. Sci. 64:11–25). Herein I report observations regarding the diet of *S. dekayi* from western Pennsylvania, USA, including the inaugural documentation of millipedes as a food item, as well as the first account specifically identifying *Lumbricus rubellus* (Red Marshworms) as having been consumed by *S. dekayi*.

While studying a population of *S. dekayi* at a site along the Hwy 832 bridge in Erie Co., Pennsylvania, USA (42.09375°N, 80.14180°W; datum WGS84), several observations were made regarding the species' diet. At 1950 h on 24 August 2012 a juvenile female *S. dekayi* (SVL = 145 mm; 2.5 g) was discovered under a panel of particle board on a slope dominated by herbaceous vegetation. While being measured, the snake disgorged the following slugs: *Arion hortensis* complex (N = 1), *Arion* sp. (N = 1), *Deroceras* sp. (N = 2), and one unidentified slug. Also disgorged were two millipedes of the order Julida. The combined mass of the prey items was 0.12 g.

Between 31 May 2012 and 19 September 2012, dietary data were gathered from an additional eight *S. dekayi* (SVL = 114–225 mm; 1.5-7.5 g). Two *S. dekayi* had each consumed a single *L. rubellus*, while another disgorged an unidentified earthworm. The remaining five *S. dekayi* had consumed slugs, three each disgorged a single slug: *Arion* sp., *Deroceras* sp., and *D. reticulatum*, respectively. The remaining two *S. dekayi* regurgitated multiple slugs: one disgorged three *D. reticulatum*, the other disgorged two *Arion* sp., one *Deroceras* sp., and an unidentified slug.

Of the nine *S. dekayi* that disgorged prey, seven were found between 1838–2000 h. Three of these snakes disgorged prey that were still alive; two slugs and a *L. rubellus*. Ernst and Ernst (2003. Snakes of the United States and Canada. Smithsonian Books, Washington, DC. 668 pp.) noted that *S. dekayi* forage most often in the early evening or at night. The fact that live prey was disgorged in the evening suggests that this may be the case at the Erie Co. site as well. The remaining two *S. dekayi* were found in the morning between 0921–1124 h and only contained dead prey.

To my knowledge, this is the first report of millipedes in the diet of *S. dekayi*. The millipedes consumed by the *S. dekayi* captured on 24 August might have been consumed incidentally. Mucus secreted by *Arion* slugs during routine handling was especially sticky (pers. obs.). Millipedes were plentiful under cover objects with slugs and snakes, and it is foreseeable that nearby invertebrates could adhere to a slug being manipulated during predation. It is possible that the remains of insects and mites observed by Judd (*op. cit.*) might have also been ingested accidentally. Although earthworms have previously been reported in the diet of *S. dekayi*, this is the first report specifically identifying *L. rubellus* as a prey item. *Lumbricus rubellus* is a European exotic earthworm usually found in surface litter or under debris (Reynolds 1977. The Earthworms [Lumbricidae and Sparganophilidae] of Ontario. Life Sci. Misc. Publ., Royal Ontario Museum, Toronto, Canada. 141 pp.). Like *L. rubellus*, the slugs (*Arion* sp. and *D. reticulatum*) consumed by *S. dekayi* at the Erie Co. site were European exotics. Although it was not possible to identify most of the disgorged *Arion* slugs to species, *A. subfuscus* was the most prevalent species found at the site. Likewise, *D. laeve* was found at the site in very small numbers, while *D. reticulatum* was much more abundant. Snakes were released at the site of capture; prey items were preserved and will be deposited in the invertebrate collection of the Natural History Museum at the Tom Ridge Environmental Center, Erie, Pennsylvania, USA.

I wish to offer my gratitude to both Jeff Beane and George Pisani for suggestions and comments that improved the manuscript.

BRIAN S. GRAY, Natural History Museum at the Tom Ridge Environmental Center, 301 Peninsula Drive, Erie, Pennsylvania 16505, USA; e-mail: brachystoma@hotmail.com.

***ZAMENIS SITULA* (Leopard Snake). DIET AND FEEDING BEHAVIOR.** On 22 August 2012, at 0053 h, one of us (PC) observed an adult female *Z. situla* (SVL = 590 mm; tail length = 140 mm; 52 g) preying on a subadult *Mus musculus* (House Mouse). The observation took place on a roadside separated from an olive grove by a blackberry bush, ca. 1 km SW of the town of Cavallino, Lecce Province, southeastern Italy (40.30°N, 18.18°E, datum WGS 84; elev. 41 m). The snake was not preserved, but its morphological examination leaves no doubt as to its specific identity (2 pre-ventrals + 231 ventrals, anal scale divided; 75 subcaudals, divided except for the first six; pupil round; dorsals smooth, vertebral row not enlarged; 25 dorsal scale rows at midbody; 8 supralabials on each side, 4^{th} + 5^{th} contacting the eye; 9 infralabials, 1 loreal, 1 preocular and 2 postoculars on each side; spotted dorsal pattern). The snake was released at the place of capture and the mouse was deposited in the collections of the Museo di Storia naturale del Salento. Rare and poorly known, *Z. situla* is reputed to be diurnal or occasionally crepuscular (Fattizz 1996. Anfibi e Rettili della Penisola Salentina. Physis Ed., Latiano. 125 pp.; Rugiero et al. 1998. J. Herpetol. 32:626–630). Our observation seems to represent the first reported case of nocturnal feeding by this snake in the wild.

We thank Antonio Durante (Cavallino) for his hospitality during our field work.

Amphibians and Reptiles of the Carolinas and Virginia, 2nd edition

Jeffrey C. Beane, Alvin L. Braswell, Joseph C. Mitchell, William M. Palmer, and Julian R. Harrison III, with photographs by Jack Dermid. 2010. The University of North Carolina Press, Chapel Hill (www.uncpress.unc.edu). 274 pp. US $26.00. Softcover. ISBN 978-0-8078-7112-6/ Hardcover. US $56.00. ISBN 978-0-8078-3374-2.

JEFF BOUNDY
Louisiana Department of Wildlife and Fisheries, PO Box 98,000, Baton Rouge, Louisiana 70898-9000, USA
e-mail: jboundy@wlf.la.gov

The sight of an amphibian or reptile manifests a curiosity that is usually expressed through two questions: "what is it" and "what does it do?" For the person who knows what "it" is and does, the sighting raises other questions about whether or not the observation is normal regarding its appearance, location, seasonal activity, reproduction and other aspects the animal's natural history. Rarely is an informed individual present to answer those questions. Instead, guides that summarize the fauna of geographic regions and provide summary natural history data serve as vicarious experts to a state's citizenry, and to that purpose *Amphibians and Reptiles of the Carolinas and Virginia* is exemplary.

The book's format is standard for a regional summary. The introduction is only eight text pages long, without subheadings, but manages, in that short space, to inform the reader about the scope of the book. It outlines the herpetofaunal diversity of the covered area in a passionless two-page summary of taxonomy and nomenclature and continues with discussions of introduced species and conservation (with an unfortunate emphasis on "listings"). There is an admonition to be careful and conservation-minded when searching for and collecting animals, laws regulating take are mentioned (although no specific rules are detailed), and there is a reserved discussion of pet-keeping. The format and arrangement of species accounts are presented, clues useful in identifying animals are provided, and there is a solicitation of new records. Finally, there is a caution about snake bites (but no suggestions about what to do when bit).

The physical characteristics of the Carolinas and Virginia are described (eight pages of text, a map, and seven photographs of habitat) through discussion of physiographic provinces, characteristic vegetative associations, and climate. Another eight pages discuss the history of herpetology in the region. This section has the liveliest prose in the book. It begins with 16th century reports of the fauna, the serendipitous advent of 18 th and 19 th century resident naturalists, followed by the arrival in each state of one or more individuals whose observational skills and prolific writing form the foundation for continued research in the Carolinas and Virginia.

A list of the native and non-native species of amphibians and reptiles separates the introductory material from the species accounts. Classic generic assignments are retained, with current generic names listed in parentheses (e.g., *Eumeces* (*Plestiodon*) *fasciatus*). Each class, order, and suborder receives about one page of descriptive material that characterizes each from a global perspective. Each species account is likewise brief. The amount of text for each account, with few exceptions, appears to be governed by the amount of space available on a single page that also must accommodate a color photograph and range map. Where additional space is required for text, the size of the photographs suffer (e.g., *Bufo americanus*). The species text includes a description, comparison with similar species, description of geographic range and habitat, food (for some species), reproductive data, and conservation status. Description of calls are provided for anurans. All of the information is provided in a little over 200 words per species. Few species are illustrated by more than one photograph, and there is rare mention of subspecies. Species accounts are followed by a thorough glossary, 52 literature references, and a dozen websites for private organizations, museums and universities.

A notable inconsistency in the book is the difference in which species distributions are displayed on the maps. Those for North Carolina are the most precise, portraying a minimal known range, but those of South Carolina and Virginia often appear over generalized and stop abruptly at the North Carolina borders (e.g., *Plethodon cinereus, Lampropeltis triangulum*). I was curious about the discontinuity in ranges of some species (e.g., *Hyla gratiosa, Pantherophis guttatus*) in northern North Carolina, but found no explanation. The color photographs are excellent. Characteristic markings and morphological features for most species are evident, highlighted for example by photographer Dermid's clever means of showing the color pattern of the inner thigh on *Hyla femoralis*, and his positioning of *Rana catesbeiana* and *R. grylio* to compare extent of the hind-foot webbing between the two species. For a few, however, diagnostic markings are not portrayed, such as the long neck, broad forearm bands and striped "pants" of *Deirochelys*.

For those familiar with the first edition of *Amphibians and Reptiles of the Carolinas and Virginia* (Martof et al. 1980), I provide the following comparisons. The number of species has increased from 159 to 189, nearly all through the discovery of cryptic salamander species. Except for three plethodontid species complexes, the second edition provides equal coverage for the new species that have been added during the span of 30 years, and the new species are illustrated by high quality, diagnostic photographs. The range maps show greater detail of distribution, primarily by reducing the broad-brush display of the first edition. The text size is smaller in the second edition, and is presented as two columns, allowing more text to be packed in per page. Some wording is changed (e.g., hellbenders are described as "ugly, slimy and large" in the first edition, vs. "impressive" in the second). The

second edition introduces the term "biodiversity" and has eliminated the first edition's statement that amphibians and reptiles "do well in captivity and make amusing pets." Standard photograph size is 10.5 × 7 cm in the first, vs. 10 × 6 cm in the second edition. Most of Dermid's photographs are retained in the second edition, including some new ones. However, several dozen have been replaced, I suppose to better portray diagnostic features. The new *Rana palustris* photo shows the bright yellow undersurface of the tibia, but the paired, square dorsal blotches are better featured in the first edition. The new *Rana sphenocephala* photo is more typical in coloration of the species, though the characteristic white tympanic spot is obscure.

Except for the history chapter, the book is devoid of personality despite (or perhaps because of) being authored by seven individuals. The text has been masterfully crafted to eliminate all excess wording, and is concisely informative about each topic the authors have elected to cover. It presents a lesson in being succinct—descriptive biology in the form of "one-liners." The citizens of the Carolinas and Virginia can now arm themselves with an updated, highly portable means of identifying and learning about that which creeps or slithers into their comfort zone.

Geckos: The Animal Answer Guide

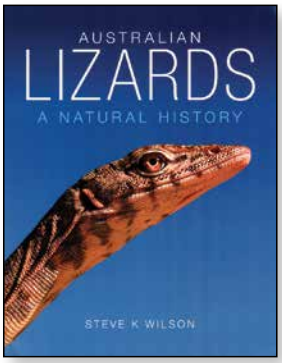
Aaron M. Bauer. 2013. Johns Hopkins University Press, Baltimore, Maryland. Softcover. xiv + 159 pages. US $26.95. ISBN 978-1-4214-0852-1.

JOSEPH R. MENDELSON III
Department of Herpetology, Zoo Atlanta
800 Cherokee Ave SE,
Atlanta, Georgia 30315, USA
e-mail: jmendelson@zooatlanta.org

This is a fantastic book. Anyone who has had the pleasure of hearing author Aaron Bauer give a lecture will find here that he can write in the same manner—eloquent, clear, easy to understand, yet packed with information. I could hear Aaron's voice in my head while I read this book. As the introductory pages make clear, this book is not a husbandry guide for pet enthusiasts because there are plenty of those available. Nonetheless, there are frequent mentions of topics central to the interests of pet enthusiasts and this book will be well valued by the burgeoning ranks of people keeping geckos as pets, as well as any general naturalist, and all persons interested in herpetology at any level. Honestly, I don't personally know a whole lot about geckos and I learned quite a bit from this book. For example, I have worked a bit with *Thecadactylus rapicauda* in the field for about 20 years, and learned from this book that they parachute between branches, using their extensively webbed feet. Bauer has a gifted approach here that is fully readable by enthusiasts of almost any age and background, yet he includes depth in his text that will inform the practicing comparative biologist. That is not an easy balance to achieve in writing, and Bauer got it impressively right in this book.

The question-and-answer format of the Johns Hopkins Press *Animal Answer Guide* series veers this book refreshingly away from a standard textbook format, yet the organization and well prepared index make information easy to find. The book has handy internal references, to guide readers to related topics appearing in other sections of the book. The style of the book does not allow for traditional academic in-line literature, but a suitably complete bibliography appears at the end. An unusual chapter entitled "Geckology" reviews the history of scholarly study of geckos. This is a very nice nod to the tradition of science that could well encourage a young herpetologist to explore the academic literature. Similarly, an appendix includes the names of virtually all relevant professional societies and journals. I would have greatly benefitted from a list like this when I was first trying to navigate the academic world while in high school. Another scholarly nod is the index including the current taxonomy of geckos, nicely including their IUCN Red List rankings. The chapter on geckos in human culture has far more depth than the after-thought feel that similar chapters in other books often have. Similarly, I greatly appreciated the double perspective approach used to treat the topics of "influences of geckos on humans" and "influences of humans on geckos" as I found it refreshingly original and perfectly balanced. These sorts of attentions are testament to Bauer's evident attempts to positively encourage gecko enthusiasts toward the basic academic efforts that inform this very book. Bauer is being inclusive here, and clearly wants everybody to feel like they can join and contribute to the fascinating world of discovering the mysteries of geckos. This is a gracious approach that really allows this book to bring very technical information across to every interested reader. A particular jargon-packed sentence here or there may serve to make the reader want to learn more, rather than dissuade anyone. As a singular example, I will point to the concise and perfectly accurate summary of the different types of squamate chromatophores and pigments presented on page 42. I've never seen this admittedly complex topic better simplified and summarized, with no loss of basic information; very impressive. I nominate Aaron Bauer to write an *Animal Answer Guide* for every major clade of reptiles and amphibians, and then we will collectively have the ultimate useful textbook for our herpetology courses, and one that the students will actually read.

The production values are generally excellent. I found no spelling typos, and only a handful of awkward spacing/justification issues. Assumedly to keep prices affordable, most images appear in black-and-white, with two sets of well-chosen color plates to highlight certain appropriate taxa. Images are credited to many photographers, but those by Tony Gamble and Lee Grismer really stand out as especially well composed. A few of the black-and-white images are a bit dark and the image discussing the camouflage value of green coloration in *Nautilinus grayi* does not work well in black and white imagery. The image of the inverted hemipenis is well lit, but its close-in perspective makes it a bit disorienting; a related image of the cloacal spur in males of some species (described well in the text) would have been a useful addition. But overall, the black and white images are perfectly suitable to their task. The only information gap I found was in the excellent section describing vision and structure of the eye. I fully thought we were leading into a description of the functional difference between circular and elliptical pupils, but I didn't see it. But I did see a great summary of the function of rod



and cone cells in squamates, and I learned for the first time that geckos see in color at night!

What really permeates this book is Bauer's life-long passion and experience with the geckos of the world. No one else could have written this book with both the top-tier academic authority and also the in-hand love of geckos that Aaron Bauer has. His first-hand experiences, his knowledge, and his admiration for the incredible animals make this book ultimately readable for the broadest range of audiences. This is a fine piece of work and I am really glad I read it in its entirety. While Bauer works on the companion volumes for the remaining clades, I strongly recommend this book for everyone, at any level of interest. No matter which taxa you claim to study, go read this book.

Australian Lizards—A Natural History

Steve K. Wilson. 2012. CSIRO Publishing, Collingwood, Victoria, Australia (in USA and Canada distributed by Stylus Publishing; www.styluspub.com). x + 196 pp. Softcover. AUS $49.95 (approx. US $46.00). ISBN 9780643106406.

AARON M. BAUER
Department of Biology, Villanova University, 800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA
e-mail: aaron.bauer@villanova.edu

"Lizards are juicy and nutritious" begins Chapter 6 of this new book on Australian lizards. Not since Edgar Waite's (1929) description of geckos as "soft and flabby to handle" have I appreciated a herpetological turn of phrase this much!

This may look like a picture book, but it is so much more. Steve Wilson is known for his excellent photographs of reptiles and amphibians (e.g., Wilson and Knowles 1988; Wilson 2005; Wilson and Swan 2010) and this book does not disappoint. More than 400 color photos strikingly capture the diversity of the Australian lizard fauna. In addition to standard portraits, there are many "action shots" of lizards eating arthropds, arthropods eating lizards, lizards hatching and being born, threatening, thermoregulating, and mating. Throughout the photos are of good to excellent quality. There are great photos of *Pygopus* feeding on a spider (p. 116), various lizards copulating (p. 143–145), a Central Military Dragon (*Ctenophorus isolepis*) caught in the act of defecation (p. 133), and a Garden Skink (*Lampropholis delicata*) with an unimaginable mite load (p. 100).

A photo of fighting male *Nebulifera robusta* (p. 142) dramatically shows off the gekkotan ability to withdraw the eye deep into the socket and examples of geckos (*Diplodactylus conspicillatus*, *D. tessellatus*) using their tails in defensive postures (p. 107) are striking. Of special note are a series of photos illustrating camouflage in geckos and agamids (pp. 94–96); that of *Phyllurus platurus* shows one of the best color matches to substrate I have ever seen (p. 94). I am especially impressed by the photos of limbless and reduced-limbed taxa. These can look like so many pieces of spaghetti, but Wilson has brought out their character, and the diversity of these forms, especially *Lerista*, can really be appreciated.

Come for the photos, stay for the text; it is well-written, detailed without being off-putting to non-specialists, and it serves as a crash course in Australian lizards, their diversity and biology. Although the title of the book is rather similar to Greer's (1989) *The Biology and Evolution of Australian Lizards*, Wilson's book has much more in common with Greene's *Snakes, The Evolution of Mystery in Nature* (1997) or Pianka and Vitt's *Lizards, Windows to the Evolution of Diversity* (2003). Greer's book is a treasure trove of information for herpetologists, a concise summary of data on Australian lizards, but this book is aimed at a more general audience. It is a "gateway" book—the kind that can really spark the interest of budding herpetologists, or even convert the non-herpetologically inclined. I defy anyone with even the slightest interest in the natural world not to be interested in Australian lizards by the time they finish the book.

The book is organized topically rather than taxonomically. After "Meet the Lizards," an introduction to diversity, the book is arranged into chapters such as "Senses: sight, scent and sound," "How lizards manage their water," and "The fate of Australian lizards." The last of these discusses the effects of cane toads and fire ants on lizards, as well as the more familiar and universal issues of changing land use and habitat loss. A series of somewhat more detailed sidelights are presented as "boxes." One deals with the rediscovery of the Pygmy Blue-tongue skink, *Tiliqua adelaidensis*, in 1992 and another with the Pedra Branca Skink, *Niveoscincus palfreymani*, Australia's southernmost totally terrestrial vertebrate, which lives on a tiny rock in the Southern Ocean. Yet another is devoted to the origin of the names "wood adder" and "stone adder" for certain species of *Diplodactylus* geckos. I will leave it to readers to discover the source.

Although the emphasis is definitely Australian, there are a few non-Australian taxa shown or discussed (e.g., *Phrynosoma* and *Furcifer* to illustrate lingual feeding). Taxonomy is as up to date as can be for the local taxa—several new Australian genera that were proposed in 2011 and 2012 (*Uvidicolus*, *Nebulifera*, etc.) are used. However it is less current for some extralimital taxa. For example, *Cnemidophorus uniparens* is used instead of *Aspidoscelis* (p. 147). Typos and misstatements are few and far between in this book. I noted only a few instances each: *Sceloporus poinsettia* is misspelled *poincettii* (p. 64), Mertens' Water Monitor is rendered as Merten's (p. 167), the number of Australian varanid species, given as 27, is said to be "about half of the world's total" (p. 8), but the current tally for varanids is actually 73, *Rhacodactylus* (now *Correlophis*) *ciliatus* can regenerate their tails (contra p. 98), although they often do not, and, in the glossary, the term "pleurodont" is incorrectly defined as an attachment type in which teeth are "set in sockets."

Unfortunately for those whose interests are piqued by particular topics, there are no citations in the text itself, making it difficult to track sources for specific information. However, the references section contains about 215 entries representing a diversity of sources up through 2011, so there is an access point into the literature. Interestingly, although some more general works are included among the technical papers listed, the ultimate classic of Australian herpetology, Cogger's *Reptiles and Amphibians of Australia* (2000) is not. The book concludes with a single index combining common names, scientific names and major subjects.

This book is an ideal gift for any novice herpetologist—in Australia or not. It is also appropriate for any Australian or visitor to Australia who wants to better understand the natural world. Even seasoned herpetologists, familiar with all of the topics discussed, will find new appreciation for Australian lizards through the stunning images.

Students working on amphibians of western Equatorial Africa have been spoiled in recent years. Right after the publication of an identification key to the amphibians of Gabon and Equatorial Guinea (Frétey et al. 2011), here is a remarkable book on the treefrogs of Cameroon. It is authored by the French biologist Jean-Louis Amiet, who vies with the Swiss Jean-Luc Perret the title of the best and most productive specialist on Cameroon amphibians. Jean-Louis Amiet is not only an amphibian specialist, he is a living encyclopedia with an extensive knowledge and active research activities on the flora and fauna of tropical Africa. This new, voluminous, solidly bound book, entirely in French, is divided into four main parts: general remarks (pp. 9–50, including a key to genera, an introduction to the physical geography of Cameroon with 26 beautiful landscape photographs, and a methodology section), hyperoliid treefrogs (pp. 51–431), the genus *Leptopelis* (pp. 433–562), and finally a chapter on poorly known species and under-prospected geographical areas (563–569). The literature section (pp. 571–576) includes 150 references, 31 of them authored or co-authored by Amiet, the most recent dating from 2009. Taxa covered belong to the Arthroleptidae (*Leptopelis* Günther, 1859) and Hyperoliidae (*Acanthixalus* Laurent, 1944, *Afrixalus* Laurent, 1944, *Alexteroon* Perret, 1988, *Arlequinus* Perret, 1988, *Cryptothylax* Laurent & Combaz, 1950, *Hyperolius* Rapp, 1842, *Kassina* Girard, 1853, *Opisthothylax* Perret, 1966, and *Phlyctimantis* Laurent & Combaz, 1950). The rhacophorid treefrogs *Chiromantis* (represented in Cameroon by *C. rufescens* (Günther, 1868)) were not included "in order to preserve the taxonomic homogeneity of the opus." In total, 62 species are covered, among them 24 *Hyperolius* spp. and 16 *Leptopelis* spp., i.e., a bit less than a third of the ca. 200 amphibian species currently known from Cameroon.

Species accounts systematically include references to the original description and sections on adult morphology, pattern and color, sexual dimorphism, eco-ethology, and distribution. Depending on the species, some accounts also include sections on tadpole morphology, parasitism, taxonomic issues, or phylogenetic relationships. Each species account is illustrated by one or two plates of color photographs taken by Amiet (with the exception of the photograph of *Afrixalus schneideri* [Boettger, 1889], in black and white and taken by Perret—this is the only species that is not illustrated alive in color in the book), one or two plates showing superb drawings made by Amiet (dorsal patterns, webbing, tadpole, vocal sacs, etc., depending on the species), activity cycle graphs, and a point locality distribution map. In all there are 667 photographs of live individuals, with up to ten individuals per photograph. The distribution maps, limited to Cameroon, also show the major vegetation zones and the areas above 600 m asl. Illustrated identification keys to *Hyperolius* and *Leptopelis* species are provided, as is comparative table for *Alexteroon* spp. that can be used as a key.

Attention should be drawn to some taxonomic points presented in the opus, especially because some some of them might be overlooked by non-French speaking readers. Amiet describes a new subgenus of *Afrixalus*, *Laurentixalus* Amiet, 2012 with *Afrixalus laevis* (Ahl, 1930) as type-species. It is said to include, besides the type-species, *A. lacteus* Perret, 1976, *A. dorsimaculatus* (Ahl, 1930) and *A. uluguruensis* (Barbour & Loveridge, 1928). Amiet makes a detailed comparison between *Leptopelis aubryi* (Duméril, 1856) and *L. spiritusnoctis* Rödel, 2007, concluding that they are synonymous. He regards *Hyperolius dintelmanni* Lötters & Schmitz, 2004 as a subspecies of *H. tuberculatus* (Mocquard, 1897). He retains *Hyperolius pallidus* Mertens, 1940 as a subspecies of *H. nitidulus* Peters, 1875, and maintains *Chlorolius* Perret, 1988 as a subgenus of *Hyperolius*. He treats *Phlyctimantis boulengeri* Perret, 1986 as a subspecies of *P. leonardi* (Boulenger, 1906) and regards *Leptopelis occidentalis* Schiøtz, 1967 as a subspecies of *L. boulengeri* (Werner, 1898). In the species account of *Leptopelis brevirostris* (Werner, 1898), Amiet merely suggests that the tympanum-less *Leptopelis crystallinoron* Lötters, Rödel & Burger, 2005, which he says is known from a single female, might be just an aberrant specimen of the former species, while later in the book (p. 515) he unambiguously treats them as synonyms. The synonymy had already been noted by Frétey et al. (2011) who mentioned their resemblance and referred to a personal communication by Amiet who had informed them that he had seen a *L. brevirostris* that was missing a tympanum on one side of its head. Both Frétey et al. (2011) and Amiet (2012) seem to have been unaware of the additional morphological differences

explained in the original description and the rediscovery of that species by Bell et al. (2010; see Pauwels and Chirio 2012). Amiet regards *Leptopelis macrotis* Schiøtz, 1967 as a subspecies of *L. millsoni* (Boulenger, 1895). The book additionally makes corrections to mistakes made in the literature, by Amiet himself or by others, especially with respect to species identifications.

The text of this new book is fluid, pleasant to read, and there are few typographical errors. It has two exceptional qualities. First, it is abundantly illustrated with drawings (about 900!), graphs, and color plates. The drawings are exceptionally accurate. They represent a huge effort; for example, drawings of foot webbing each required about six hours of work (Amiet, pers. comm., May 2013). All photos are outstanding, and they were all taken in Cameroon (their localities and dates are provided in an appendix). Morphological and pattern variations are well represented. Unusually-patterned specimens are shown as well, but they are always clearly indicated as such in the figure captions (the exceptional nature of these specimens could be overlooked by non French speaking readers).

Second, the book suggests numerous directions for future research. Several populations potentially representing new species or subspecies are discussed in detail, with photographs of representatives of these (Manki *Hyperolius riggenbachi* (Nieden, 1910), Mount Cameroon *Kassina* cf. *maculosa* (Sternfeld, 1917), *Leptopelis* cf. *bocagii* (Günther, 1864), *L.* cf. *christyi* (Boulenger, 1912), Mwandong *L.* cf. *modestus* (Werner, 1898), Lena *L.* cf. *notatus* (Buchholz & Peters, 1875), and many others), and all the available information that could help to locate the additional specimens that will eventually allow their taxonomic status to be resolved. Under-prospected areas that might reveal interesting records are listed. Amiet has literally spoon-fed future batrachologists and professors in need of subjects for their students the descriptions of numerous frog taxa. Hopefully this will be capitalized upon. Jean-Louis Amiet is currently working on botanical publications and will then work on butterfly publications before working again on amphibians (Amiet, pers. comm., May 2013); one will thus have to curb one's impatience to see the next publications of Amiet on Cameroonian amphibians. In the meantime, we encourage scientific libraries, batrachologists, and students to acquire and exploit this remarkable and beautiful book.

Acknowledgments.—We are grateful to Jean-Louis Amiet (Nyons) and Thierry Frétey (Médréac) for providing useful information and literature, respectively, and to Yves-Marie Allain of La Nef des Livres for sending a review copy of the book.

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

REPRINTS AND PAGE PROOFS

Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not prepared for natural history, geographic distribution, or herpetoculture notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. High resolution electronic (pdf) reprints of notes, articles, book reviews, and obituaries are provided at no charge to the primary/corresponding author as a benefit of SSAR membership. Reprint files will normally be sent prior to the issue mailing date from the printer. Authors who are not current SSAR members may purchase pdf reprints from the SSAR Publications Office.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at the Department of Natural Sciences, Williams Baptist College, P.O. Box 3692, Walnut Ridge, AR 72476, USA. Periodicals postage paid at Walnut Ridge, AR 72476 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.

POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive prepublication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1–880	check website below for current pricing
INDEX TO ACCOUNTS 1–400: Cross-referenced, 64 pages	$6
INDEX TO ACCOUNTS 401–600: Cross-referenced, 32 pages	$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)	$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)	$35
INCOMPLETE SET: NUMBERS 1–190	$75
191–410	$85
411–840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its bulletin, *Herpetological Review*, both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:

WELCOME LETTER FROM THE NEW SSAR PRESIDENT
ROBERT D. ALDRIDGE

PHOTO BY LINDA ALDRIDGE

It is a recent tradition for new presidents of SSAR to introduce themselves to the membership and to give some sage advice to its younger members. I was born at home in south St. Louis, Missouri, the fourth child of five. I attended St. Anthony's grade school and St. Mary's high school. As a child, I was fascinated with amphibians and reptiles, especially snakes. In the city of St. Louis there were populations of Dekay's brownsnake (*Storeria dekayi*) and the lined snake *(Tropidoclonion lineatum*). I joined the Boy Scouts of America at a young age, primarily for the camping trips and other opportunities to get out of the city. I remained active in the scouts for years and achieved the rank of Eagle Scout.

Following graduation from high school, I enrolled at the University of Missouri, Columbia. After telling my advisors of my interests, they recommended that I enter the Forestry school because snakes are found in the woods. I eventually enrolled in the wildlife program.

The highlights of my undergraduate education were summer jobs with the United States Fish and Wildlife Service. In the summer of 1965, I worked at the Mark Twain National Wildlife Refuge in Grafton, Illinois and the following year at the Upper Souris NWF in North Dakota. In both jobs I worked primarily on banding and censusing wildfowl, but I did manage to make lists of the amphibians and reptiles present. I then enrolled in the Master's of Arts Biology program at the University of Missouri. I was Dr. Dean (Doc) Metter's first graduate student. For my thesis, I worked on the reproductive biology of the Western Wormsnake (*Carphophis vermis).* I completed my MA in 1969 and enrolled in the Ph.D. program at the University of New Mexico. I was one of six graduate students who worked in the Museum of Southwestern Biology under the mentorship of Dr. William Degenhardt. My dissertation research at UMN was on the reproductive cycles of the Prairie Rattlesnake (*Crotalus viridis*) and the Glossy Snake (*Arizona elegans*).

Following graduation, I was hired by Saint Louis University in 1973 and I begin my 41st year there this summer. Throughout my years at SLU, I have been fortunate enough to pursue my childhood passion and study the biology of amphibians and reptiles. Although much of my data comes from museum collections, I have had the opportunity to do extensive fieldwork in the various parts of the US, Mexico, and Guam. I have published over 50 articles on reproductive biology and morphology of amphibians and reptiles and recently co-edited, with David M. Sever, the *Reproductive Biology and Phylogeny of Snakes* (Science Publishers, Inc., Enfield, NH).

In July, SSAR will have its 56th annual meeting at UNM in Albuquerque. I look forward to reuniting with Bill Degenhardt and many of the graduate students with whom I shared so much at UNM.

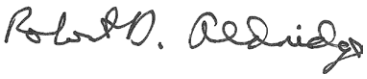
My Service to SSAR

My first position in SSAR was Translations Coordinator (1978–1990). I was responsible for making available to the membership translations of important scientific papers and arranging for the translation of scientific papers. From 1988 to 2001, I served as Publications Secretary and from 1997 to 2001 I also served as Treasurer. I was elected President-elect in 2012 and now serve as President (2013–2114). I feel that my service to SSAR is really a privilege for me. I get to work with many dedicated individuals who also appreciate the importance of professional societies and share an appreciation for amphibians and reptiles. To paraphrase a colleague on the importance of meetings: I have several friends, very close friends, that I met because we share a common interest and passion for amazing fishes, amphibians, and reptiles. At meetings, I always learn new things, I meet young students who are our "lifeblood." We will only persist as a society if we bring young people into our organizations. The price of membership is unimportant compared to the value of my friendship with other professionals because those friendships are priceless.

Threats to Professional Societies

I believe the greatest threat to science today is the demise of national/international professional societies. This is not unique to herpetological societies. Professional societies rely on membership to publish journals, host meetings, etc. All of the officers and editors are volunteers. These people are dedicated to this effort because they believe in the importance of a peer-reviewed journal. Members belong to societies primarily to get these publications.

The advent of electronic journals has its value, but also some negative aspects. Some groups feel it is important to make all herpetological material available for free. In an ideal world SSAR would like this also. But in reality, there are expenses associated with publishing a professional journal, sponsoring meetings, providing student research and travel support, publishing books, etc. Individual memberships in societies account for the majority (>50%) of the income. If the content of journals is posted for free, there is little incentive for people to become members of societies. A sudden drop in membership would quickly result in the demise of the very journals that some feel should be free for all. **No one wins if this occurs.** Keep in mind that journals, even electronic journals, have a difficult time surviving without the support of society membership (e.g., *Herpetological Natural History*, 1993–2003; *Contemporary Herpetology* 1998–2009). What may occur is that so-called "vanity presses," which say they are peer-reviewed but are mostly pay to publish on-line operations, will be the future of herpetology.



The Importance of Participating in Professional Societies

I strongly urge young members to attend the national/international meetings. The meetings are a great place to meet others with similar interests, whether they are established researchers or novices. At our meetings, there are numerous papers and posters that represent the wide diversity of research on herps. Meetings are expensive, but SSAR, and other societies, make efforts to reduce

those costs for students. SSAR has travel grants that students can apply for and also have hotel rooms that can be shared. There are numerous student competitions that offer monetary awards. To further encourage student participation, SSAR will have its 2015 meeting at the University of Kansas (30 July 30 to 3 August 2015). To keep expenses low, we will have arranged for dorm rooms and a dining plan to be available. There will be a social specifically designed for new members to meet senior herpetologists. We also have planned a tour of the Fitch Natural History Reserve, a live herp display, a Herp Quiz, and a graduate student social.

What You Can Do

If you have an interest helping SSAR, or another society, attend a board meeting. These meetings are generally scheduled for the first day of the Joint Meeting of Ichthyologists and Herpetologists. All of the societies have important committees or positions that require relatively little time, yet are essential to the organization. If you unable to make the board meeting, attend the SSAR/HR Student Social. You need to register for this on the JMIH web page. I thank you for your support of SSAR and hope to see you at our annual meeting. If you have any questions please feel free to contact me at: aldridge@slu.edu.

Robert D. Aldridge
President

ABOUT OUR COVER: *Duellmanohyla soralia*

The genus *Duellmanohyla* includes eight species of small Central American hylid frogs that collectively range from southeastern Mexico to northwestern Panama. These arboreal frogs are typically found near small cascading mountain streams and are generally characterized by the adults' red eyes and the tadpoles' large pendant funnel-shaped oral discs (Köhler 2008. Reptiles of Central America, 2nd ed., revised. Herpeton Verlag Elke Kohler). The Honduran Brook Frog (*Duellmanohyla soralia*) is a species frequently encountered in the cloud forests of northwestern Honduras and eastern Guatemala. Unfortunately, this charismatic species was previously common but now in decline across its range, likely due to a combination of habitat degradation and amphibian chytridiomycosis (Cruz et al. 2010. *Duellmanohyla soralia*. *In* IUCN 2012. IUCN Red List of Threatened Species. Version 2012.2. <www.iucnredlist.org>. Downloaded on 19 April 2013). Currently it is listed as Critically Endangered in the IUCN Red List of Threatened Species and exists only in a patchwork of isolated populations. Cusuco National Park, Honduras, represents the largest "protected" area of critical habitat for the species, but a recent intensification of illegal deforestation within the park's most protected core zone habitat is now threatening this stronghold.

The adult frogs are quite attractive with bright red eyes and cryptic dorsal patterns of greens and browns, often resembling lichen. Although amphibian tadpoles are rarely considered attractive, larvae of this species are quite magnificent, both in appearance and behavior. Flecks of metallic emerald-green pepper their olive to nearly black bodies, with eyes that become increasingly red with age. Despite possessing large pendant oral discs commonly used to cling to rocks near cascade currents, *D. soralia* tadpoles are instead often found swimming upside-down in large schools behind boulders that break the currents and create calm whirlpools. In this inverted fashion, the tadpoles feed by skimming particles from the film at the water's surface.

Although the adult population in Cusuco National Park appears to be more stable than other sympatric hylids, moderate levels of infection with amphibian chytrid fungus have been detected in the species (40%), primarily in tadpoles and recent metamorphs, and subadult animals are becoming increasingly uncommon (Kolby et al. 2010. Diseases of Aquatic Organisms 92[2]:245–251). Plans to begin an *ex situ* management program incorporating both head-start/reintroduction and captive assurance population establishment are now being developed in Honduras and will be located at the Honduran Amphibian Rescue and Conservation Center. These activities will help buffer against future populations declines caused by disease and/or habitat degradation and work to ensure long-term survival.

The cover image depicts four larval *Duellmanohyla soralia* schooling behind a rock and feeding upside-down at the water's surface. The tadpoles were encountered at night in a cloud forest stream of Cusuco National Park, Honduras, during the first targeted field survey for amphibian chytrid fungus in the country. The image was taken in 2007 with a Nikon D200 DSLR, Sigma 180mm macro lens (f/16, ISO200, 1/250 sec.), handheld, and illuminated by a single Nikon SB800 flash.

The photographer, **Jonathan Kolby**, is a PhD Candidate at James Cook University investigating global dispersal mechanisms of amphibian chytrid fungus and ranavirus. He previously worked as a CITES Policy Specialist with the US Fish & Wildlife Service and has a particular interest in the international wildlife trade and biosecurity. Since 2007, Jonathan has been monitoring amphibian chytrid fungus in the endangered amphibians of Cusuco National Park, Honduras, to document the long-term dynamics of disease in the wild. In response to worrisome observations, Jonathan is now working to build in-country capacity and establish the Honduran Amphibian Rescue and Conservation Center, to prevent the extinction of three critically endangered species (*Duellmanohyla soralia*, *Plectrohyla dasypus*, and *P. exquisita*).

NEWSNOTES

PARC 2013 Alison Haskell Award Winner

The Alison Haskell Award for Excellence in Herpetofaunal Conservation is presented by Partners in Amphibian and Reptile Conservation (PARC), in memory of Alison Haskell (1956–2006). This award is intended to recognize an individual from North America who exemplifies extraordinary commitment to herpetofaunal conservation, has been overlooked by other means of acclaim, has displayed exemplary commitment to building or strengthening partnerships, and has displayed distinguished career-long contributions to partnerships and herpetofaunal conservation.

We are proud to announce that the 2013 recipient of the Alison Haskell Award is Charles Painter. Charlie is currently the Endangered Species Herpetologist for the New Mexico Department of Game and Fish. Charlie's career-long contributions to herpetofauna conservation, leadership roles, and ability to build effective partnerships make him a very deserving winner of this award.

Painter will receive his award at the Southwest PARC meeting held in conjunction with the JMIH in Alburquerque, New Mexico in July.

Reptile Database Update

A new version of the Reptile Database was released in March 2013. This brings the total number of species to 9,789 (up from 9,741, i.e. plus 48, including resurrections etc.) and the total of literature citations to 31,315 (+674), including 89 published in 2013. The synonymies of 1960 entries have been updated since last time (mostly by adding chresonyms), added references to 1270 species, updated the distribution of 252 species, and edited the comments of 380 species. Overall, almost 4000 species have been edited since the last update.

Selected Taxonomic News and Changes

Anolis. After serious contemplation (and consultation with several experts) we changed the names of anoles back to *Anolis*. For some reasons see Poe et al. (2013) Zootaxa 3626:295–299.

Teiidae. The names of many teiids have changed following the suggestions of Harvey et al. (2012) Zootaxa 3459:1–156. However, we are already getting complaints that this may not be tenable.

Hydrophiinae. This was done already in December 2012, but do note that the names of many sea snakes have been changed too, following Sanders et al. (2013) Molecular Phylogenetics and Evolution 66(3):575–591.

Laudakia. We changed the names of many *Laudakia* species, following Baig et al. (2012) Vertebrate Zoology 62(2):213–260.

Australia. We went through all Australian names and updated them, if necessary, based on Wilson & Swan (2010) and a few more recent taxon-specific papers. The last wholesale review of Australia was based on Cogger (2000) so this needed some verification.

Plestiodon. Now up to date based on Brandley (2012) Zoological Journal of the Linnean Society 165(1):163–189.

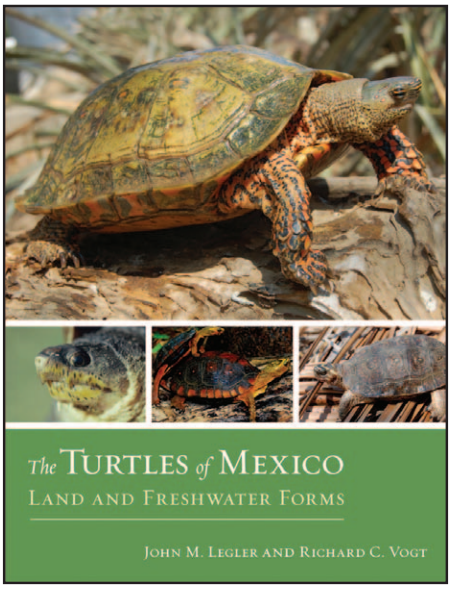
Hoser names. We follow Kaiser et al. (2013) synonymizing most of the names that Raymond Hoser has proposed over the past years, but most recently in a series of papers published in 2012. See Kaiser et al. (2013) Herpetological Review 44(1):8–23, for details or simply search the database for reference = Hoser.

Palearctic naked-toed geckos (*Cyrtopodion* etc.). Revised based on Bauer et al. (2013) Zootaxa 3599(4):301–324.

Hobart Smith (1912–2013) passed away in early March. Until recently he was probably the most productive reptile alpha taxonomist alive with more than 100 new reptiles described (Uetz 2010. Zootaxa 2334:59–68) and reportedly more than 1500 papers published. Aaron Bauer now holds this crown with about 125 new species, even though he has to catch up in terms of papers.

Volunteers needed: With a backlog of about 700 papers we have trouble keeping up! If you want to help out, let us know your area of interest, so we can send you a few papers to curate. Most importantly, we need your help to extract taxonomically important information, which you then should send in a format that we can easily add to the database (e.g., new/changed names, references, distribution data, etc.). We are working on a partly automated system to ask authors for help, but it may take a little while until this is in place.

Internships: We have openings for 1 or 2 paid internships, at least for a couple of months. However, you will be required to show up in Richmond, Virginia, at least once. Contact Peter Uetz (phu878@gmail.com) if you are interested.



Global checklist: With this release, we have posted a global checklist of all reptiles with their higher taxa online. It's available as an Excel spreadsheet here: http://www.reptile-database.org/data/reptile_checklist_2013_03.xls.zip.

Literature database: As indicated, we have now more than 31,000 references in the reptile database. More than 15,000 are available via weblinks (although often via commercial publishers). Send us URLs of your web pages if you make your own papers available online or send us links to BHL when they are missing in our database.

More details on changed names, etc. are listed on our news page: http://www.reptile-database.org/db-info/news.html.

MEETINGS

Mexican Turtles Symposium

Dick Vogt is organizing a session on Mexican turtles in celebration of the publication of *The Turtles of Mexico, Land and Freshwater Forms*, by John M. Legler and Richard C. Vogt, University of California Press. This session will be held at the annual Symposium for the Conservation and Biology of Tortoises and Freshwater Turtles, hosted by the Turtle Survival Alliance (TSA) in St. Louis, Missouri, USA, 7–10 August 2013. Meeting attendants will be able to purchase the book from UC Press for a 20% discount. The book has 260 color photos most of them never published before, line drawings, maps, and 430 pages of text. Much new material never published anywhere before, compiled by the combined field work in Mexico of over 50 years by Legler and Vogt. Dr. Legler will also be the keynote speaker at the TSA meeting. Visit http://www.turtlesurvival.org/ for meeting information and registration, space is limited.

If you would like to participate as a speaker in the symposium on Mexican species of turtles, please contact Dick Vogt. Posters are also welcome. We already have a dozen speakers committed including: Jim Berry, Taylor Edwards, John Iverson, Pat Minx, Suzanne McGraugh, Oscar Flores Villela, Marco Antonio Lopez-Luna, Miguel Angel de la Torre Loranca, Martha Harfush, Gracia Porter Gonzalez, Michael Pappas, and Jim Berry.

Travel Grants are limited, however a few have been reserved for those in the Mexican session. In order to apply for travel support you must first register and submit your abstract and then fill out the travel grant application at http://www.turtlesurvival.org/. For questions or additional information, please contact Dick Vogt (e-mail: vogt@inpa.gov.br or dickturtlevogt@gmail.com).

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

8–10 July 2013—Southwest PARC (Partners in Amphibian and Reptile Conservation), Albuquerque, New Mexico, USA. Information: http://www.swparc.org/

10–15 July 2013—Joint Meeting of Ichthyologists and Herpetologists (SSAR, HL, ASIH), Albuquerque, New Mexico, USA. Information: http://www.dce.k-state.edu/conf/jointmeeting/

21–25 July 2013—26th International Congress for Conservation Biology, Baltimore, Maryland, USA. Information: http://www.conbio.org/mini-sites/iccb-2013

22–26 July 2013—VI Congresso Brasileiro de Herpetologia, Salvador, Bahia, Brazil. Information: http://www.cbh13.com.br/

31 July–3 August 2013—36th International Herpetological Symposium, New Orleans, Louisiana, USA. Information: http://internationalherpetologicalsymposium.com/index.html

22–27 August 2013—SHE 17th European Congress of Herpetology, Veszprém, Hungary. Information: http://seh2013.org/

13–15 September 2013—6th Symposium on the Ecology, Status, and Conservation of Diamondback Terrapins, Seabrook Island, South Carolina, USA. Information: http://www.bio.davidson.edu/terrapin2013/Welcome.html

17–20 September 2013— XIV Congreso Argentino de Herpetologia, Centro Nacional Patagonico (CENPAT-CONICET) and Universidad Nacional de la Patagonia San Juan Bosco, Puerto Madryn, Chubut, Argentina.
Information: xivcongresoherpetologia@gmail.com or avila@cenpat.edu.ar/morando@cenpat.edu.ar

25–29 September 2013—Annual Meeting of the German Society for Herpetology and Herpetoculture (DGHT), Bonn, Germany. Information: www.dght.de

3–6 October 2013—4th Biology of Vipers Conference, Struga, FYR Macedonia. Information: www.shdmr.org/vipers

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Beck Wehrle or Ben Lowe; e-mail addresses may be found on the inside front cover.

Thermal Tolerances of the World's Southernmost Gecko

Most animals have a narrow range of temperatures at which they can function. Knowing the thermal tolerances of ectothermic species across their geographic range is essential for understanding their distributions and how they will be affected by changing climates. *Homonota darwinii*, the world's southernmost gecko, faces great thermal challenges as a nocturnal lizard with a wide South American range. As different *H. darwinii* populations experience a broad range of temperatures, the authors of this recent study expected this species to exhibit increased thermal tolerance with increasing latitude. Geckos were collected from four sites in southern Argentina spanning the latitudinal range of *H. darwinii*. For a year, data loggers collected hourly temperatures in gecko retreats at each site to determine the actual temperatures the geckos experience. The authors determined critical thermal minimums in the lab by lowering the temperature 0.2–1°C per minute until geckos flipped onto their backs could no longer right themselves. Because critical thermal maximum is very close to the lethal maximum temperature in *H. darwinii*, the authors measured panting threshold, raising the temperature 0.5°C per minute until the geckos panted for at least three seconds. They found that the annual minimum and maximum temperatures experienced by the geckos varied considerably by population with the northernmost population experiencing the greatest temperature variation and the southernmost experiencing the least. Geckos from the northernmost populations had the lowest critical thermal minimums, a pattern unexpected based on the lower latitudes of the sites, but expected due to the high elevations. Additionally, these thermal minima were lower than those seen in other gecko species, even reaching sub-freezing temperatures. Broader thermal tolerances occurred with higher environmental temperature variation. The panting thresholds did not vary across populations, a pattern seen in other ectotherms. This may be because of behavioral thermoregulation at extreme high temperatures, including inactivity during the time of day when it is hot. The authors suggest that some populations of *H. darwinii* may not be greatly affected by climate warming because these high temperatures occur while the geckos are at rest in retreats, yet those in thermally heterogeneous habitats with narrower tolerances may be affected by climate change.

Weeks, D. M., and R. E. Espinoza. 2013. Lizards on ice: Comparative thermal tolerances of the world's southernmost gecko. Journal of Thermal Biology 38:225–232.

Lack of Shelter has Cascading Consequences for Snakes

Shelter use can serve essential roles for animals and has been well studied as a way to buffer extreme temperature conditions. Yet, shelters are also used for a number of other ecologically significant functions, such as sleeping, reproduction, and digestion. Considering the importance of shelters, depriving an animal of this resource is expected to increase physiological stress and possibly disrupt a myriad of other functions. The authors of this study measured thermoregulation, digestion, and plasma corticoid levels (an indicator of stress) in Aspic Vipers (*Vipera aspis*) over multiple temperature/shelter configurations and feeding states. In a four-treatment choice experiment, fed and unfed snakes were given access to a hot and a cold compartment, each with either a shelter or no shelter. Snakes more often chose the compartment with a shelter, regardless of temperature. When no shelters were available, snakes chose the hot compartment. When both compartments had shelters, slightly more snakes chose the hot compartment. These patterns were found in both fed and unfed snakes. In a second experiment, fed snakes were placed in either a hot or cold compartment with or without a shelter and had their feces collected for digestive analysis, including transit time measurement and an estimate of assimilation. About two-thirds of these vipers were subjected to daily simulated predator attacks with a leather glove. Another group of unfed snakes had their plasma corticoid levels measured 10 days after being placed in one of the hot/cold, shelter/no shelter compartments. Vipers in hot compartments have shorter digestive transit times than those in cold compartments, but shelter did not affect transit time. "Predator attacks" reduced transit time in all groups, though more so in hot habitats. Regurgitation was common in cold compartments, twice as frequent when the snake lacked a shelter, and even more increased in "attacked" snakes (though this was not affected by shelter availability). All regurgitating snakes assimilated less of their prey than snakes that were able to digest normally. Plasma corticoid levels were much higher in snakes lacking both heat and a shelter than in each of these states alone, indicating high snake stress due to this interaction. Though in some of their experiments, snakes provided with heat appeared to be less stressed even if lacking a shelter; this forced the vipers to increase their temperature and thus energy expenditure, possibly to compensate for increased predation risk. Availability of shelter can greatly affect the temperature, energy expenditure, digestion, and stress in snakes. Shelters play an important role in habitat selection and the authors suggest shelter availability and quality should be incorporated into conservation and captivity concerns.

Bonnet, X., A. Fizesan, and C. L. Michel. 2013. Shelter availability, stress level and digestive performance in the aspic viper. The Journal of Experimental Biology 216:815–822.

Salamander Contact Zones Show Climate Variation and Suggest Interspecific Competition

Geographic ranges of species pairs that abut each other and are stable over time provide interesting opportunities for studying the determinants of species range limits. In habitats with environmental gradients, abiotic factors are thought to govern range limits; in homogeneous areas, competition or other biotic factors may direct these borders. Combinations of these factors have also been previously experimentally supported. The ranges of the widely distributed *Salamandra salamandra* (Fire Salamander) and the pre-montane/montane *S. atra* (Alpine Salamander) meet in the European Alps. The authors of this study gleaned distributional information for these species from museum records, with random background points from within the species' distributions added to represent available habitats. Climatic conditions of salamander habitats from 1961–1990 were characterized using GIS-layers with a 100 m x 100 m resolution. From this, five non-correlated climate variables were identified for further analysis of each species' climatic niches in the contact zone. Using species distribution modeling (SDM) and a multivariate analysis, the authors developed null-distributions and null-models of niche overlaps. They compared the actual species distributions and niches to find that *S. atra* were found in a wider range of climate conditions than *S. salamandra*. This was unexpected as *S. atra* had a narrower geographic range. *S. salamandra* were found in drier areas with less solar radiation. The climatic variables differed among the three contact zones, and the western zone was narrowest when compared with the central and eastern contact zones. The main predictors of the *S. atra* SDM were mean annual precipitation and slope of habitat, and in the western contact zone, mean temperature in January. *S. salamandra* SDM predictors also varied by contact zone: for the central and eastern zones it was January temperature, while in the west it was radiation in July and slope. Yet at all contact zones, the two species were found to have a moderate niche overlap, though lower than predicted by the null-model, supporting the sharp climatic gradient as an important factor in maintaining the hybrid zones. However, when range-wide thermal tolerance breadth and variation was taken into account, the absence of *S. atra* from apparently suitable habitats suggests that its distribution is most likely limited by competition. *S. salamandra*, on the other hand, is likely most limited by abrupt climatic changes as they have a narrower abiotic niche. This study provides support for the role of abiotic factors determining species boundaries and identifies biotic interactions as a likely influence as well. The authors suggest mechanistic species distribution models may add to the understanding of the salamanders' climatic niches and physiological tolerances.

Werner, P., S. Lötters, B. R. Schmidt, J. O. Engler, and D. Rödder. 2013. The role of climate for the range limits of parapatric European land salamanders. Ecography (*in press*) doi: 10.1111/j.1600-0587.2013.00242.x

Hot Frogs Less Susceptible to *Bd*

Chytridiomycosis, caused by the fungus *Batrachochytrium dendrobatidis* (*Bd*), is responsible for massive amphibian declines around the world. Yet in numerous cases, amphibians that have been infected with chytrid in some populations coexist with *Bd* in others. Some infected individuals may not show symptoms in the field, others uninfected in the field may become highly sensitive to *Bd* in the lab. In one study, chytrid-positive frogs had increased body temperatures, possibly to produce "behavioral fevers" for escape of *Bd*'s optimal growth temperatures of 17–25°C. In this study, three *Litoria* species (Hylidae: *L. lesueuri*, *L. serrate*, and *L. nannotis*) that have suffered different degrees of *Bd*-related declines were swabbed for *Bd* and tracked at four sites in excess of two weeks during the wet season in Australia. The dorsal temperatures of re-sighted frogs were recorded at each observation (on average 17 times per individual). Infection prevalence was the same among sites, but different among species. On average, individuals with body temperatures greater than 25°C had decreased incidence of *Bd* infection. Infection was particularly rare if greater than 75% of an individual's body temperatures exceeded 25°C. Males of the two most vulnerable species, *L. serrate* and *L. nannotis*, had the highest infection rates, with females of those species exhibiting moderate infection prevalence. This is the first study to show that thermal behavior in the field affects *Bd* infection probability. These findings do not support frogs elevating body temperature as a response to infection, but rather that elevated temperatures prevent infection or do so coincidentally while serving other physiological functions. This study underscores the importance of body temperature on host-pathogen interactions. Variation in individual thermal preferences may allow for evolution of higher thermal tolerances, possibly increasing amphibian survival against the threat of chytridomycosis.

Painted Turtle Genome Offers Insights into Chelonian Phylogeny, Evolution, and Physiology

The unique morphologies, physiologies, and life histories of turtles such as extreme environmental tolerances, tooth loss, temperature dependent sex determination, and longevity have long made them a curiosity to researchers. Additionally, as the placement of turtles in the tree of life has long been an enigma, genome-wide analyses offer important information for understanding the evolution of this unusual clade. The authors of this study sequenced the nuclear genome of a female Western Painted Turtle, *Chrysemys picta bellii*. Using a combination of next-generation shotgun sequencing and Sanger sequencing of paired-end BACs, the authors constructed a scaffold with an N50 size of 5.2 megabases and over 93% coverage of the genome. They then compared 1955 homologous genes across eight vertebrate

taxa to build a phylogenetic tree. Their results strongly support turtles as the sister clade to Archosauria and show the turtle genome has been evolving very slowly. The Western Painted Turtle has a one of the highest tolerances of oxygen deprivation of any vertebrate, even relative to other turtles. RNA transcripts collected from hearts and brains of Western Painted Turtles exposed to anoxic and normal-oxygen conditions showed considerable upregulation in 19 heart genes and 23 brain genes. These results reveal regulatory changes in conserved vertebrate genes as mechanisms for the evolution of anoxia tolerance. Comparing the genes of *C. picta bellii* to those of a less freeze-tolerant turtle (*Apalone spinifera*) and humans identified a novel microRNA associated with freeze tolerance. Five previously identified tooth-specific genes had premature stop codons or were greatly degraded, similar to patterns found in birds, though turtles accumulated these mutations at half the rate. Aging related genes from other taxa were looked for in *C. picta bellii* and other turtle genomes. Two genes were found to be absent across all sampled turtles, suggesting further investigations should be made into their role in senescence. Through phylogenetic reconstruction, temperature dependent sex determination was identified as the ancestral condition in turtles, with genetic sex determination likely evolving multiple times. Comparisons with the genomes of eight other vertebrates identified gene families likely responsible for the unique characteristics of turtles as a whole. These findings open further investigation into the genes and regulation of turtle genomes, as well as the implications for advance the understanding of turtles' extraordinary traits.

Shaffer, H. B., and Colleagues. 2013. The western painted turtle genome, a model for the evolution if extreme physiological adaptations in a slowly evolving lineage. Genome Biology (*in press*) doi:10.1186/gb-2013-14-3-r28.

Salamanders Provide Evidence for an Early Isthmus of Panama

The Isthmus of Panama has long been recognized for its dual role as a barrier and conduit for dispersal. Though most researchers have operated under the premise that the Isthmus opened for overland travel less than four million years ago, geological and phylogenetic studies finding evidence in support of an earlier connection between North and South America have been accumulating. In this paper, the authors present results from a phylogenetic study of South American representatives of the plethodontid genus *Bolitoglossa*, and in doing so add to the growing debate over New World biogeography. This group of salamanders undoubtedly originated in Central America and southern Mexico, where the vast majority of its species diversity still resides. Nevertheless, 28 *Bolitoglossa* species occur in South America, most of which are endemic to the continent. The researchers collected genetic sequence data on for two genes (one mtDNA, one nuclear DNA) for 60 exemplar specimens including 15 South American *Bolitoglossa*. Using these sequences and a Plethodontidae crown group age of 75 million years as a calibration point, they constructed a time-calibrated "species-tree" phylogeny. The resulting phylogeny presented a monophyletic South American *Bolitoglossa*, with two instances of South American species expanding their distributions north into Central America. They found evidence for considerable cryptic diversity, as three of their South American samples did not closely align with currently recognized species. The crown age of the South American *Bolitoglossa* clade was found to be 23.6 million years. It is theoretically conceivable that diversification began prior to the formation of the land bridge, and independent lineages simultaneously dispersed south subsequent to land bridge formation while also simultaneously going extinct north of the bridge. However, the great differential between diversification timing and land bridge formation coupled with the number of lineages that would need to have accomplished this feat makes this hypothesis unlikely. And while the estimated timing of bolitoglossine diversification relative to the plethodontid crown age is much older than recovered in other analyses that employed greater gene and lineage sampling, this discrepancy is not sufficient to realistically fit the recovered genetic diversity of this clade into four million years. And while overwater dispersal to South America remains a possibility, even for taxa that are unlikely candidates for this dispersal scenario, each example such as this shifts the weight of evidence slightly further to a continental scale phenomenon such as an early Panamanian land bridge. Additionally, this study finds evidence for considerable cryptic diversity among South American *Bolitoglossa*.

Elmer, K. R., R. M. Bonett, D. B. Wake, and S. C. Lougheed. 2013. Early Miocene origin and cryptic diversification of South American salamanders. BMC Evolutionary Biology 13:59.

Cane Toads Modulate Muscle Length When Landing

Jumping requires the coordination of two mechanical phases: positive acceleration during take off and negative acceleration during landing. For hopping animals such as anurans, landing in a controlled manner is important for decreasing the risk of muscle damage. The anconeus, or forelimb muscle, in Cane Toads (*Rhinella marina*) is important to dissipating the mechanical energy experienced during landing. Muscles, however, are more likely to sustain damage if actively stretched. In a previous study, it was found that in preparation for landing, Cane Toads fine-tune their muscle activity to in response to jump height. The authors of this study tested the hypothesis that such modulation functions to shorten the frogs' anconeus muscles, decreasing the likelihood of muscle damage. Electromyography (EMG) transducers were implanted into the anconeus muscles of five Cane Toads. Muscle activity and fascicle length were recorded during hopping trials, after which the muscles were dissected out and mounted to a servomotor. Isolated muscles were stimulated at varying lengths to characterize force-length properties. The authors found that shortening of the anconeus muscle before landing occurred was inversely correlated with hop distance. They infer that this is to dissipate energy as the muscle is stretched during landing and thus protecting the muscles from damage caused by going beyond optimal length. Indeed, the anconeus

muscle is engaged well in advance of landing, extending the toad's elbow and altering the length of the muscle at impact. Thus, the anconeus muscle does not get stretched beyond its optimal length and the maximum length at the end of landing does not vary with jump distance. Yet this restriction is likely a trade-off with muscle force capacity. This study reveals that frogs are able to modulate both their muscle recruitment and the length of their muscle when landing to incur the least damage when landing.

Survey of *Bd* in Cameroon Finds First Record in Caecilians

Amphibian declines caused by chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) have been well documented in frogs and salamanders. *Bd* is hypothesized to have originated in Africa, yet a recent survey of northeastern Cameroon showed no incidence of the pathogen. Considering that a 70-year old museum specimen from Cameroon tested positive for *Bd*, as did amphibian populations from surrounding countries, the authors of this study conducted follow up surveys of Cameroon's diverse amphibian fauna to investigate these conflicting results. Across 12 sites, 108 amphibian species (including four caecilian species) were screened for *Bd* through skin swabs or toe clips, for a total of 1137 individuals sampled. Samples were analyzed for *Bd* using a quantitative PCR protocol. Overall, 10.9% of samples tested positive for *Bd*, with an average of 32.0% prevalence per site. Three sites had no detected *Bd* and one site, Rumpi Hills, had only one infected individual. Infection intensity was low for all positive specimens. Across all sites, 6.7% of frogs and 64.2% of caecilians were positive for *Bd*. This is the first record of *Bd* in caecilians. Of note, this may be the largest sampling of caecilians tested for chytrid. There are conflicting results as to whether there are differences in infection intensity between frogs and caecilians. The Mt. Oku site showed considerable between-year variation in *Bd* prevalence, perhaps accounting for the negative results of the previous survey. Since amphibians from some sites were not shown to have Bd whereas other ecologically similar populations were positive, Cameroon may be a model locale to track amphibian-*Bd* interactions to better understand how to manage this pathogen in other parts of the world, though more work is necessary to understand how native Cameroonian amphibians are affected by *Bd*. Additionally, Cameroon may serve as a source for *Bd* spread and thus is important to monitor for amphibian conservation considerations.

No Within-Clade Trade-offs in Chameleon Foot Performance

Chameleons have highly specialized morphology including ballistic tongues, independently movable eyes, and prehensile tails and feet. The grasping ability of these lizards' feet and tails is thought to be an adaptation to their arboreal niches. Previous studies have shown faster running species from divergent chameleon clades to be poorer at gripping with their feet, probably due to differences in the mechanical requirements for these activities. To test if this pattern is generally present or the result of clade-specific adaptations, the authors examined the morphology and locomotor performance of closely related pairs of terrestrial (*Chamaeleo namaquensis* and *Bradypodion occidentale*) and arboreal (*C. dilepis* and *B. damaranum*) chameleon species. They collected lizards from the wild and measured snout–vent length, femur, tibia and lateral hindfoot length, and humerus, radius and lateral forefoot length. Using microtomography (an x-ray technique that generates images similar to CT-scans), they produced three-dimensional images of each species. Chameleons were recorded gripping a dowel attached to a force platform for 60 seconds. During the trial, individuals were pulled away from the dowel and allowed to reattach repeatedly. This method was also repeated for forefoot-only measurements. Additionally, chameleons were chased down a 2-m track to measure sprint speed. Both arboreal species had longer phalangeal elements and fused carpals, absent in both terrestrial chameleons. Generally, though, morphological and performance differences by habitat type were dependent on clade. Arboreal species had higher grasping strength and speed, as well as larger hands and feet. Hand size was the best predictor of grip strength. Larger hands and feet may be beneficial for stability on larger perch diameters. In the terrestrial chameleons, unfused carpals may allow for increased flattening of the feet to better grip a flat surface. The two *Chamaeleo* species had no differences in sprint speed, yet the arboreal *Bradypodion* sprinted faster than the terrestrial *Bradypodion*. Thus, trade-offs in gripping and running are more an effect of phylogeny than functional habitat use alone.

Developing an Undergraduate Herpetology Club at Cornell University

In its 20 years of existence, the Cornell Herpetological Society (CHS)—an undergraduate herpetology club at Cornell University in Ithaca, New York—has reached several hundred students. It has shaped their college experience and in many cases their careers. Undergraduate herp clubs like the CHS provide opportunities that students could not gain through coursework alone, such as peer mentorship, field experiences, teaching opportunities, interactions with established scientists, and the opportunity to take on a leadership role. These groups create a community of students with similar interests who can amplify each other's curiosity outside of a strictly academic setting, often leading to lasting friendships beyond graduation. Because the CHS has positively influenced the lives and careers of its many undergraduate members, it could serve as an example to inspire the creation of similar groups at more universities. Ultimately, connections among several university herp clubs could provide additional opportunities and ideas.

FIG. 1. CHS members examine and photograph a salamander during a local field survey.

FIG. 2. By conducting systematic surveys each fall and spring of properties owned by a local land conservation organization called the Finger Lakes Land Trust, the CHS contributes to the Land Trust's and other herpetological databases.

Three Cornell undergraduates who were devoted to the scientific study of amphibians and reptiles founded the CHS in 1992. Since then, it has operated continuously on a model based on leadership from a group of undergraduate officers, with advice and guidance from its faculty advisor Kraig Adler. Although the CHS is organized and run by undergraduate students, it welcomes participation from the broader Cornell and Ithaca communities. The CHS is a registered student-run organization that must apply for funding each semester along with over 800 other student organizations at Cornell University. The CHS organizes three main activities: 1) monthly meetings in which local or visiting speakers present their work; 2) field trips that include short excursions into the field and longer, multi-day visits to universities, museums, and zoos for behind the scenes tours with staff; and 3) educational programs that provide outreach to the community. Each of these activities has served to enrich the lives of herp club undergrads and other community members.

Monthly Meetings

True to its mission as a club run by students primarily for students, the CHS now reserves its first meeting every year for a series of talks by more senior club members based on their summer research or other biological activities. New students benefit from other undergraduates discussing their research, recently including topics as diverse as lizard mating systems in the American Southwest, toad colonization of Alaska, or Brazilian frog phylogeography. More senior students show new students how to seek out funding for their own research projects, demonstrating that one can, in fact, become a budding scientist while still an undergraduate. Other meetings during the academic year feature scientists, conservationists, wildlife photographers, veterinarians, and more, allowing students to learn about different types of careers. Speakers have included Aaron Bauer, Carl Gans, Chris Jenkins, Joseph Mendelson, Robert Murphy, and Margaret Stewart, among many other accomplished herpetologists. After each meeting, a casual dinner at a local restaurant allows students to have closer interactions with the guest speakers.

Off-Campus Activities

Field trips, both local day trips and multi-day excursions farther afield, give an inside look into different applications of herpetology. The club makes the most of the herp diversity in

Fig. 4. Behind the scenes at the Philadelphia Zoo, CHS undergrads get up close and personal with a tortoise named Bubba and many other herps, some of which are never exhibited.

the region by focusing the majority of outings locally. Many of those trips are with a conservation organization called the Finger Lakes Land Trust, which has the CHS conduct herp surveys on their various properties each semester (Figs. 1, 2). The club has frequently sent those data to the New York Herp Atlas project. The CHS also takes advantage of the annual spring salamander migrations to witness explosive breeding events. Last year the CHS began collaborating with Cornell's natural areas and arboretum staff to form a plan for protecting salamanders as they cross roads and for educating the increasing number of people who go to see the migration each spring. Additionally, an annual trip to southwestern New York with a staff member from the New York State Department of Environmental Conservation lets students spend a day finding hellbenders, collecting data about them, working on habitat restoration projects, and releasing juveniles head-started by the Buffalo Zoo (Fig. 3).

Members of CHS take at least one annual trip to locations farther away, including Boston, New York City, Philadelphia, Toronto, Ann Arbor, Washington and other cities around the eastern United States. The club uses these trips as a way to visit museums, zoos, or university labs, often meeting curators, veterinarians, and researches at multiple institutions over the course of a weekend (Figs. 4, 5). Students choose the location at the beginning of the year, and then the faculty advisor arranges the trip.

Educational Outreach and Community Benefits

The club benefits the larger university and local communities through educational outreach. Every year members of the CHS take reptiles and amphibians to university residence halls, Cornell's annual veterinary college open house, local schools, the Ithaca Science Center, and community centers to educate people about these oft-misunderstood creatures (Fig. 6). Most of the people who attend these programs leave feeling less afraid of herps than when they arrived, while some even leave with a newfound love of herps and other creatures. Occasionally, parents from the community bring their children to join the herp club on local field trips and at its meetings, thus fueling the next generation of herpetologists.

Club members who participate in outreach programs develop strong public speaking skills that often help them in their subsequent careers. They learn how to effectively engage an audience, an ability that serves them in a variety of situations, whether they go into research, conservation, environmental law, or another career.

Other Activities

Members of the CHS have taken advantage of several opportunities outside the club's regular activities. Some arose in the form of summer research projects, grants, or internships that the students heard of from other club members or from the club advisor. Others received research funding from an anonymous donor who provides funds to the CHS. For example, three undergrad club members used this source and other funding to do a survey of herpetofauna in Papua, New Guinea, during which they discovered a new frog species that presently holds the world record for smallest known vertebrate (see their article in PLOS One, at http://www.plosone.org/article/info:doi/10.1371/journal.pone.0029797). A few years prior to that, CHS undergraduates participated in a faculty search for a herpetologist in Cornell's Department of Ecology and Evolutionary Biology. The CHS members interviewed each candidate, and then wrote a report on each. The search committee took their recommendations

quite seriously because the CHS members took the process so seriously, and ultimately chose the candidate whom the herp club had recommended. Such experiences played a formative role in the subsequent academic and career pursuits of the students who participated in them.

Finally, the CHS fosters friendships by bringing students together. Outside of formal club activities, students get together for fun events like herp-related movie nights, holding potluck dinners, and watching such outlandish films as *Life in Cold Blood, Anaconda*, or *Snakes on a Plane*. They also go on hikes or camping trips together to take a break from school. These informal activities help relieve student stress while creating a more tightly-knit club.

Post-Herp Club Careers

Many club alumni remember their CHS days fondly as a formative influence. One of the club's founders now directs a worldwide conservation organization called Amphibian Ark, and returns to Cornell from time to time to give talks, help, and advice to current undergrads. Other members have become university professors or museum curators. Some of them did not previously recognize the possibility of building a career in research until they joined the CHS. Other alumni have pursued careers as zoo or private veterinarians, or medical doctors. Many who chose fields outside of biology or conservation for their careers remain interested in herpetology, including a couple of environmental lawyers and one computer programmer who spends his free time describing new species of turtles. In dozens of cases, the presence of an undergraduate herpetology club has fueled people's enthusiasm during college, providing a jumping off point for a lifelong interest in reptiles and amphibians.

Throughout the history of the Cornell Herpetological Society, a few dedicated students have sustained the meetings, field trips, and community outreach that left a lasting impact on so many. Similar undergraduate-driven herpetology clubs can thrive anywhere provided they have certain critical components. First and foremost, enthusiastic and focused students must manage to find each other, and then they must sustain a high enough level of involvement in the club to organize events. Nearly as important is guidance and mentorship from an advisor who truly cares about the club and its members. Such an advisor provides continuity and has the expertise to help students plan the best meetings and field trips possible. A third important component is funding, which many universities provide to student clubs through student activity fees. However, funding plays a less crucial role than do the students and faculty advisor. Even without money, clubs may hold local excursions, herp-themed movie nights, meetings, and much else. Different regions in the world have different resources to offer, so as long as students (with an advisor's help) can recognize those resources, then they can create a very successful organization.

Members of the CHS sincerely hope that students will find a way to use whatever resources they have—human, ecological, or institutional—to engage their peers outside of classrooms and labs, leaving a lasting contribution on their campus as they explore their passion.

OBITUARIES

Herpetological Review, 2013, 44(2), 188–195.
© 2013 by Society for the Study of Amphibians and Reptiles

In Memoriam: David Alfred Chiszar (1944–2013), with Reflections from Colleagues and Friends

The herpetological community lost one of the shining lights in the field of ethology and comparative psychology when David A. Chiszar, known for his pioneering work on social and predatory behavior in lower vertebrates, died after a long struggle with T-cell lymphoma on 3 January 2013. He was born in Sioux City, Iowa on 21 October 1944 and grew up in Perth Amboy, New Jersey. David is survived by his wife, Terri Macey, his former wife, Joan Wilson, and their two children, Adam Chiszar and Laine Chiszar, as well as his stepchildren, Kris Mayer and Daniel Mayer. He is also survived by his mother, Florence Chiszar, his sister Natalie Chiszar, and his brothers, Dan Chiszar, Al Chiszar, and Emery Chiszar.

PHOTO BY TERRI MACEY

David Chiszar at Arches National Park, Utah before he started cancer treatments.

He attended Rutgers University-The State University of New Jersey in Newark where he earned a B.A. (Psychology) in 1966, M.S. (Experimental Psychology) in 1969, and his Ph.D. in Experimental Psychology the next year. Chiszar was a NASA Predoctoral Fellow (1966–1967), NIMH Predoctoral Fellow (1967–1970) and was a Lecturer in Introductory Psychology at Rutgers.

He began and finished his distinguished professional career at the University of Colorado (CU) in Boulder where he quickly rose through the ranks: Visiting Assistant Professor of Psychology (1970–1971), Assistant Professor of Psychology (1971–1974), Associate Professor of Psychology (1974–1980), Professor of Psychology (1980–2013), Director, Undergraduate Education in Psychology (1977–1980), Chairman (1980–1983), Associate Dean, College of Arts and Sciences (1984–1985). During 1983–1984, Chiszar served as National Science Foundation (NSF) Program Officer in Washington, DC. He was recognized as an effective teacher because he received the University of Colorado Award for Excellence in Teaching (Statistics and Animal Behavior). He retired in 2011.

Chiszar was always committed to professional service. He reviewed manuscripts for *Animal Behaviour, Behavior Genetics, Behavioral and Neural Biology, Behavioral Processes, Herpetologica, Journal of Comparative and Physiological Psychology, Learning and Motivation, Psychological Bulletin, Journal of Herpetology, Psychological Record, Zeitschrift für Tierpsychologie,* and *Zoo Biology.* In addition, he was listed as a member of the Editorial Board for *Behavioral and Neural Biology, The Psychological Record, Zoo Biology, Journal of Comparative Psychology,* and *Journal of Herpetology.*

He reviewed grant proposals for the NSF and National Geographic Society. David was Vice President and Program Officer, Colorado-Wyoming Academy of Science (1975–1976) and Member of the Executive Committee of CWAS (1977–1980), Vice President and Program Officer for CU Chapter of Sigma Xi (1978–1979), and President of CU Chapter of Sigma Xi (1979–1980). He was a strong supporter of zoos and aquariums and much of his research was done at these institutions; he served as a Member of the Scientific Advisory Board at the Denver Zoological Gardens for many years.

Chiszar received about a dozen grants, three of which were from the US Department of the Interior to learn about the predatory and locomotory behavior of the Brown Tree Snake (*Boiga irregularis*) on the Island of Guam. This invasive snake has been a major contributor to the near extinction of a number of indigenous mammals and birds. Between 1987 and 2000, he explored methods of using chemical attractants to control this widespread pest. He co-edited an important volume in 1999 with Gordon H. Rodda: *Problem Snake Management: The Habu and the Brown Treesnake.*

In the early days of his career in 1968, he focused mainly on studies of learning and other behaviors in rats and fishes. Seven years later, his interests began to broaden to include reptiles and amphibians with the first papers on the behavior of aquatic and terrestrial turtles, as well as garter snakes. Papers appeared on the behavior of zoo animals, a topic of interest throughout his entire career. These included subjects such as animal communication, maternal behavior, "child" development and socialization in the zoo, courtship and copulation, and curiosity, learning, and occupational therapy (now called animal enrichment) in the zoo. In 1977, his studies included rattlesnakes, pine snakes, and garter snakes on topics like investigatory, predatory, and courtship behaviors. From that point onward, many papers were published that examined snake predatory behavior, often with two of his longtime collaborators—Charles W. Radcliffe and Hobart M. Smith.

Chiszar was remarkable in many ways. He was a physical fitness advocate, weightlifter, and motorcycle rider, taking a number of cross-country trips on his bike. Unlike some herpetologists who are misanthropes, David loved interacting with others, especially when exciting ideas surfaced. When this happened, he was radiant with excitement. Conversations were always Socratic dialectics and he never tried to dominate people intellectually, although he was certainly smart enough to do so. Early on, he

JAMES B. MURPHY

understood the value of collaboration, so often his papers included a number of co-investigators. He used zoo and aquarium collections brilliantly. Since he designed simple, elegant experiments that could be done in these settings without major disruption, zoo workers regularly invited him to work together. When he worked at these places, his easy-going style, sensitivity, and brilliance captivated all in attendance—he was a joy to be with at all times. He was always willing to review projects and drafts from zoo biologists and students, and his comments would invariably improve the final product. His wide-ranging intellect encompassed many topics—human social behaviors, politics, psychology, philosophy, theology, history of science, ophiophobia and other phobias, history of herpetoculture, art and scientific illustration among many. He was enthralled with the peculiar habits of some herpetologists and loved to talk about them with amusement; there was never condescension toward them but rather fascination with them. He was the consummate raconteur.

Recollections of David Chiszar

When I attended the joint annual meeting of the Society for the Study of Amphibians and Reptiles and The Herpetologists' League in Raleigh, North Carolina in 1982, I heard a wonderful presentation by David Chiszar on the predatory behavior of the Red Spitting Cobra (*Naja mossambica pallida*). I was entranced and invited him to join me for lunch. We talked for hours about all things herpetological and he told me that he wanted to do a comparative study on the behaviors of rattlesnakes and other pitvipers. Because we had a large collection of these reptiles at the Dallas Zoo where I was employed, mostly collected by Jonathan Campbell and Barry Armstrong, I invited him to visit and study these lovely snakes. Thus began a wonderful association with him as collaborator and later as close friend.

Imagine my surprise years later when an envelope arrived at the Zoo from the president of CU informing me by letter that Chiszar and Hobart Smith had contacted dozens of my friends and colleagues to provide letters of support for an honorary doctorate and the university was pleased to give me this extraordinary honor at the next graduation ceremony. I was thunderstruck and so grateful for this act of kindness; I will never forget their efforts on my behalf. When I traveled to Boulder for the ceremony, my parents accompanied me and expressed surprise to the university president at a luncheon that their son had somehow amounted to something by actually making a modest living as a herpetologist and was recognized as such. Later, I told Dave that issuing this degree to me would likely spell the death of Western education.

When I learned that Dave was dealing with cancer several years ago, I called on a regular basis to see how he was faring. There was no self-pity. Every time, he briefly updated me on the severe after-effects of the treatments but quickly changed the subject to herpetology. In fact about six weeks before his death, although his voice was weak and he was tired, he wanted to talk about movement patterns in Prairie Rattlesnakes so we spent nearly an hour on this topic. As he told me at the end of our conversation, "Murphy, I've lived a good life and have no regrets." That about says it all!

David was trained as a graduate student in Experimental Psychology at Rutgers, and his doctoral research focused on the comparative ethology of marine arthropods, such as crabs, lobsters, and the like. With that background he was employed at the University of Colorado, fresh from his Ph.D. Indeed, his first research setup in the psychology department there was designed to continue his doctoral line of research. At that time, consequently, he had never had anything to do with herpetology. Therefore his transformation in a relatively short time, becoming a leading, innovative experimental herpetologist, is very astonishing, almost unbelievable. Only his outstanding scholarship made it possible.

As I was the only herpetologist at CU at that time, we became fast friends. We helped each other as best we could, but our approaches were quite different, his experimental, mine descriptive. His choice of research in the change to herpetology at CU was his own, initially the feeding behavior of rattlesnakes. That especially appealed to him, not only because it had never been understood in detail, but also because his macho approach to life made it appealing.

Ultimately we shared many publications, analyzing to various degrees each other's thoughts on them as they took form. Above all, we thoroughly enjoyed field work in various western states and in northern Mexico. On such trips we had ample time for discussion of almost anything conceivable, where David's background knowledge was always an inspiration and a model for me.

David was very careful in handling snakes, including rattlesnakes, and was bitten only once, after several decades, by a Lower California Rattlesnake (*Crotalus enyo*) that he was helping to shed. He almost immediately became unconscious, barely having time to make a call for help. His survival was a very close call. Ultimately it was concluded that he had developed an allergy to venom over his many years of exposure to it. Upon his recovery he soon disposed of all of his venomous snakes. However, he had a big backlog of accumulated experimental data on the snakes that he continued to analyze and publish.

David was a fine, enthusiastic, and innovative scientist, generous in so many ways to all who knew him, and a true friend to me as we traversed the early terrain of studying reptile, especially snake, behavior. We both began with an interest in chemoreception in feeding behavior and prey recognition in snakes. We both

got started about the same time and we were those two weird guys studying snake perception in psychology departments. This association with comparative psychology as well as zoology and ethology, helped cement our friendship and mutual support over many years. I focused on natricines, primarily gartersnakes, while Dave was always most interested in the far more challenging pitvipers, especially rattlesnakes. He also did important behavioral work on gartersnakes as well as numerous other vertebrates. In fact, he was a pioneer in fostering academic – zoological park collaborations in behavioral research. In addition to his own extensive research studies on reptile behavior, Dave served in administrative capacities at NSF as well as being Chair of his department at the University of Colorado. Although Dave collaborated with dozens of scientists and students, his most sustained collaboration was with Hobart Smith, which moved him into herpetological taxonomy, bibliography, herpetological stamps and coins, and other areas quite removed from his psychological and behavioral work. He was personally generous in recognizing my own research and he and Hobart did me the honor of naming a subspecies of false coral snake for me (*Pliocercus euryzonus burghardti*).

Dave's research on snake behavior was particularly neat in that he devised clear experiments, often with innovative testing situations, but always with objective behavioral measures and straightforward and rigorous statistics. In fact, during my stints as journal editor, I often relied on Dave for statistical input and evaluation. Dave was a speculative thinker and would test his ideas. One we talked about at length was the retention of prey recognition in copperheads from presumptive ancestral species. He was a fine psychologist. For example, he applied psychophysical signal detection theory to snake behavior at a time when it had rarely been used with any animal species outside the usual suspects (rats, pigeons). Besides coming up with tests of behavioral aspects of welfare for reptiles (such as the problematic role of cleaning snake cages too often), he also came up with a novel functional aspect of play that I have frequently cited—play used by parents as a measure of behavioral competence.

Those who may not have worked with Dave will not, however, forget his talks if they attended herpetological and behavioral conferences. His were inimitable—with humor and phrasing that made them memorable. His talk on testing hot sauces on snakes (not WITH snakes) is one I always remember with smiles and fondness. Even if the scientific issue was not one of seeming great import, he presented the work with such enthusiasm, delight, and thought-provoking asides, that they were events to look forward to at meetings.

The field has lost a true scholar with much yet to contribute, and will be sorely missed.

Gordon M. Burghardt
University of Tennessee

My first contact with David Chiszar was in 1975 in response to a request for reprints involving lateral displays in lizards. In the ensuing years this led to correspondence concerning the use of zoo herp collections in behavioral research and the collaboration between academic institutions (zoology and psychology departments, and their graduate programs) and zoological parks. This approach has been fruitful in involving exotic species and in producing numerous publications.

Dave was a great University of Colorado footfall enthusiast, so much so, that when the Colorado Buffalos defeated the Oklahoma Sooners in 1990, he sent me a copy of the Boulder newspaper sports page announcing this defeat which was signed by every member (30+) of his class in Animal Behavior.

Science is like most human endeavors—people work in it and hear about other folks who share their interests and then, over the years, images grow about people you never actually meet. I never really knew Dave—I met him a few times at meetings and because we both worked on aspects of snake feeding, we had read some of each other's work. Dave was already a well-established researcher with a wide reputation when I first met him. I knew about Dave's work on strike-induced chemosensory searching (SICS) and I'd been asked by almost everyone I met in the zoo world whether I knew Dave. It was only mildly embarrassing to have to confess that I didn't know him personally, but also a little puzzling to me why most people seemed to think I should know him well.

Dave and I had attacked the biology of feeding in snakes from entirely different perspectives. Dave's approach was an experimentally-based search for the sensory foundations of the behavior that grew from his Ph.D. work. He developed marvelous experiments that provided excellent tests of hypotheses about what senses snakes were using to recognize and find prey, approaches that he and many others have exploited to flesh out the sensory world of snakes. Dave had worked with a lot of other people that I also worked with but somehow we never overlapped. It was clear from everything I heard, though, that Dave was highly regarded for reasons that go beyond his science.

The images that grew about Dave Chiszar in my mind were of a person devoted to exploring his curiosity and finding out the answers to questions he thought were good questions. He did science for the sake of fleshing out our understanding, basically, for his love of simply doing science. But there was more to Dave than just this. He brought lots of other folks into his quests—and he joined others in their quests. I think that Dave's enthusiasm for his questions sucked others into his projects and he was always able to make it seem really worthwhile. This is my image of Dave—built not on close association or years of collaboration, but from what I've heard from everyone I've talked to who knew him. I'm looking forward to learning a lot more from those who knew him well. Herpetology and sensory biology have lost a friend who gave us a new appreciation for some of the extraordinary sensory adaptations of snakes.

One of the most enjoyable experiences of having a career in academia is the opportunity to continue to learn from one's peers and colleagues. It was most rewarding, then, that I was able to do so during my many interactions with Dave Chiszar. Our mutual interests in chemosensory adaptations of rattlesnakes specifically and snakes in general brought us together a number of times, through the mail and in person. I always felt that I gained a great deal from this communication as Dave was so generous and liberal with his knowledge. I firmly believe this was largely due to his background in psychology, which also greatly contributed to his innovative and elegant experimental designs. These subsequently led to greater insight into rattlesnake

predatory behavior including the concept of the Strike Induced Chemosensory Searching that they exhibit. His work was landmark and most significant in that regard.

In addition to so generously sharing his expertise with others, Dave Chiszar was also generous in other ways. On a number of occasions he was a most gracious host to me at his home in Boulder. During one of these visits Dave took me to meet his good friend and colleague, a man whom I admire greatly, Hobart Smith. I owe Dave a debt of gratitude for an unforgettable afternoon at the Smith home. On a lighter note, I was also fortunate to experience Dave's culinary proficiency. His "Godfather Dinner," complete with the movie theme music and good conversation, will long remain in my memories as a most delightful evening. I will miss you Dave!

Shortly after finishing my Ph.D., I was pleased to run across Dave's overview of lateral displays in lower vertebrates (Chiszar 1978. Lateral displays in lower vertebrates: forms, functions, and origins. *In* E. S. Reese and F. J. Lighter [eds.], Contrasts in Behavior: Adaptations in the Aquatic and Terrestrial Environments, pp. 105–135. John Wiley and Sons, New York). Reptile ethology was still in its long infancy, and here was someone other than Gordon Burghardt, my major professor, also generalizing beyond observations of individuals and species. Dave's careful, thoughtful experimental studies of captive vipers began appearing about the same time, a series that continued throughout his productive and influential career. More than anything else his publications have impressed me with an unusual flair for posing questions in a lab setting that bore on the lives of snakes in nature.

I didn't know Dave well personally, although we corresponded and met occasionally at scientific conferences, but our one sustained interaction remains vivid in memory. In 1984, David Duvall invited me to speak at the University of Wyoming, and Chiszar drove up from Boulder so that we could all visit Duvall's nearby Prairie Rattler study site. Rumor had it Chiszar was agitated by Duvall grad student Brent Graves' ear ring, so we found a gold clip-on for my left ear and when Chiszar came over for dinner, sat him on my left as we got acquainted—resulting in several tense minutes of Dave staring and me grinning, then finally a good laugh all around. The next day was long and glorious, the landscape stunning for its wide-open austerity. We'd arrived the morning after fall's first cold snap, and thus watched the rattlers migrating to a den from their summer foraging grounds. Most dramatically, we entered a small side canyon so populated by females with clusters of babies that Chiszar's dog was tied up to avoid an accident. Duvall's research was ground-breaking, directly relevant to questions Chiszar was asking in his lab, but I doubt any of us, as we marveled over the scene, imagined just how complex rattlesnake behavior eventually would prove to be (e.g., Clark et al. 2012. Cryptic sociality in rattlesnakes (*Crotalus horridus*) detected by kinship analysis. Biology Letters 8:523–525; Saviola et al. 2013. Molecular basis for prey location in viperid snakes. BMC Biology 11:20, doi:10.186/1741-7007-11-20). And what most strikes me in recalling Dave that day is how intellectually fascinated he was by it all, what joy he seemed to find in the animals themselves and the unanswered questions.

Although I was one of Chiszar's colleagues at Boulder for 16 years (1983–1999), I saw him only occasionally; we were not research collaborators, nor did we ever teach together. I can say, however, that all it took was one visit to his laboratory to leave an indelible impression; I remember my first—and only—visit as if it were yesterday. As you probably know, he had a large lab, the main room of which was chock full of big plastic trashcans. None of the cans had a lid, but each had at least one large rattlesnake, each one seemingly meaner than the one before it. As you walked through the lab next to the cans, the snakes would begin to rattle until soon it was one loud and continuous hiss. Absolutely horrifying, or so it seemed to someone who studied tiny salamanders.

To clean home cages or keep snakes available for experiments, the reptiles were routinely removed from the enclosures with a snake hook and placed in trashcans. I guess that this was what was happening when I visited.

There can be a lot of hand-waving that replaces careful science when discussing reptile behavior. The special approach and talent David Chiszar brought to the study of reptile behavior was to craft well-designed scientific experiments relating olfactory/vomerolfaction to squamate predatory behavior. With the confidence built on these discrete results he was able to build up a larger framework of predatory behavior, discovering in the process a fundamental behavioral feature he termed SICS, Strike Induced Chemosensory Searching. In turn, this invited further tests and logical enlargement to many species of reptiles. Not only his experimental results but also his solid scientific style provided the example that would become the standard of such research.

On a personal basis, he was always generous in recognizing the experimental results of colleagues and volunteered his support to the rest of us in a collegial way that represented the best of scientific collaboration. Many fond memories rush back for me of David at meetings and in the field, which I am sure most of those who knew and worked with him also recall. I am glad for this chance to record my thanks and appreciation for his work and for the person.

I first met Dave in the early 1970s when I went to the University of Colorado to consult Hobart Smith about some forgotten herpetological issue, probably about rattlesnakes. After helping me graciously, Hobart said there was a new professor in the psychology department that I should meet and directed me down to Dave's office. Dave was studying feeding behavior in Bluegills at that time, but he had a large cage containing several rattlesnakes in a corner of his lab. I believe he was holding these for a friend or as part of a confiscation, but his infectious enthusiasm for anything animate was apparent immediately. When I mentioned that I had a collection of several species of live rattlesnakes his interest heightened and it seemed that both of us immediately realized that our futures would be bound together. I arranged for Dave and his wife to come to dinner and see the snakes and he was like a boy in a candy shop. I wanted to show him some of things they did when they ate, and he immediately saw that we

could study this behavior using statistical methods of timing and counting tongue flicks.

By the time Dave left he had already mapped out several experiments we would do with my collection, he followed up and drove to Denver repeatedly where we would be closeted in my snake rooms for hours observing and quantifying feeding behaviors in a variety of species of rattlesnakes. Dave became increasingly interested and involved in rattlesnakes, and soon he switched his entire laboratory over to snake behavioral research. (He wisely waited until he achieved tenure before taking this step). After Dave switched over his lab, most of the rattlesnake research was moved to that location and Dave pursued it with unflagging enthusiasm and a relentless work ethic that was typical of his every endeavor.

Over the next 20+ years we collaborated on many different projects, and for one three-year period, I stepped aside from my zoo work and became Dave's research associate, teaching animal behavior and running the snake lab so that he could head up the National Science Foundation for two years. This was a wonderful opportunity for me because the last year of the work, Dave and I were both there working together every day. However, this opportunity came with a price. Dave insisted that I take his statistics course to appreciate the power of statistics. I was looking forward to this with all the enthusiasm of having toenails extracted without anesthesia, but he was such an excellent and entertaining teacher that the experience was stimulating and useful, with little pain; and, as he promised, it was of great value, and changed the way I viewed experimental studies of behavior.

Because of his broad intellectual curiosity, working around Dave was always interesting. Early in our work on trailing behavior, Dave wondered if the snakes could distinguish between a trail made by an envenomated mouse and an non-envenomated one. Experiments done in the lab by several of us showed that they preferentially followed the envenomated mouse and preferentially investigated them when given a choice. Even though I had made some of the observations and the statistics confirmed the effect, Dave knew I was always a little skeptical. The last time I saw Dave, about 10 days before his death, he was very excited; one of his former students, now working in another lab, had identified a component in the rattlesnake venom responsible for causing the envenomation effect on trailing behavior and thus vindicating his earlier findings.

Dave was so much more than a valued colleague. He was friend, co-worker, and mentor; and he had an infectious enthusiasm for anything to do with herpetology or animal behavior. Once, when we needed some Rock Rattlesnakes (*Crotalus lepidus*) to study the differences in feeding behavior in a species that fed on lizards and one that fed on rodents, I talked Dave into getting out of the lab and going on a collecting trip. Since he had very little field experience at that time, I explained that we would walk up these talus slopes and carefully tap on rocks with snake hooks, whereupon the snakes would reveal themselves by rattling. He was excited by the prospect of seeing a new species in the field and actually doing some collecting. After a long walk to the site we headed up opposite sides of the talus slide. I soon became aware of a constant clatter of rocks falling and banging together, and wondered if perhaps a bear was trying to dig out a snake. I slowly worked around the hill to discover it was only Dave attacking the slope, clambering up as fast as possible, making small rockslides as he went. Nothing in his experiences growing up in New Jersey or in years of lab work had prepared him for slow quiet movement in uneven terrain. Despite this inauspicious beginning, his enthusiasm never flagged, and when we finally succeeded in finding the snakes we needed, the seed of field work was planted. Years later Dave spent a number of summers doing field work with Hobart Smith (then in his 80's) all over Colorado and in Mexico. They added dozens of locality records in Colorado, fleshing out the distribution of many poorly known species.

Charles W. Radcliffe
Denver Zoo

***

Dave was my undergraduate mentor, then a colleague through his landmark studies in reptile behavior, then a collaborator on Brown Treesnake trap development and a co-editor of a seminal volume on applied snake ecology, and finally a field partner when I occasionally caught up with Dave and Hobart in their Colorado ramblings. His greatest early influence on me was as a statistician. He taught the stats course required of all psychology majors, one dash of mathematical rigor in an otherwise squishy subject area. His course and he in particular was widely viewed therefore as a gatekeeper in what was otherwise viewed as a "gut" major. However, this was back in the days before four-function calculators were affordable. At the time, Dave himself did his calculations (including square roots, which could only be done by successive approximation!) on a mechanical adding machine. You may recall that adding machines had a button for each digit in each decimal place, and a huge lever on the side which one pulled to effect the specified multiplication or addition (the process was inverted for subtraction or division). To be fair to students who could not afford an electronic calculator, calculators of any sort were not allowed in exams, and tests in Dave's stats course included, as an appendix, pages of equations (written out by Dave in longhand) with their numerical results. The challenge, of course, was that both correct and incorrect formulations were calculated out, and one had to sift through four or five pages of possibilities to find the correct result among the many that were not. This process had the effect, whether intended or not, of whittling down the number of undergraduates in search of an effortless major (student deferments being in great demand during the Vietnam War).

Later, while working in his lab I began to really understand his scientific greatness, in his unique ability to parse each behavioral question into experiments, for Dave was a great believer in the value of the decisive, exquisitely controlled experiment. For me, his series of experiments on the role of individual envenomation as the key to strike-induced chemosensory searching in *Crotalus* stands out as a paragon of the value of a well-conducted experiment. Finding the decisive experiment may be the holy grail of science, and Dave was its master practitioner. Decades later we collaborated on a series of field and laboratory experiments on Brown Treesnake behavior that were not so salubrious (Chiszar 1990. The behavior of the brown tree snake, *Boiga irregularis*: a study in applied comparative psychology. *In* D. A. Dewsbury [ed.], Contemporary Issues in Comparative Psychology, pp. 101–123. Sinauer Assoc., Sunderland, Massachusetts), and it is greatly to his credit that he accepted the results for what they were, and acknowledged the limitations of the laboratory environment to which he was so committed.

During the period in which Dave was active in Brown Treesnake research he periodically attended our scientific conferences. Despite his somewhat peripheral involvement in the field, his talks were always the eagerly awaited highlight of the annual conferences. It is easy to see why. As in everything he did, Dave

approached the scientific challenges of the Brown Treesnake as a child approaches the gifts under the Christmas tree. As he unwrapped each scientific puzzle, he utterly charmed the audience with his sense of wonder and delight in each insight. The world was a mystery awaiting discovery, and no one enjoyed the detective work with more evident enthusiasm than Dave. He passed that zeal onto many of us, a gift that has lasted a lifetime.

Gordon Rodda
United States Geological Survey

As an undergraduate in the department of Ecology and Evolutionary Biology at the University of Colorado, I had hopes of one day pursing a graduate career in herpetology. Having grades well below the required cutoff seemed to hinder the possibility of being accepted into a graduate program, and I wanted to try to do something extracurricular, specifically research. I felt that my poor grades would keep me from gaining research experience, but one person, Dr. David Chiszar, took a chance and offered me the opportunity to work in his lab. Work with Dave during my undergraduate career quickly progressed into learning the basics of predatory behavior research with snakes, foundations of statistical analyses (by completing stats by hand—the best way to learn, Dave would always tell me) and importantly, how to avoid being bitten by a venomous snake. "Never rush," he would always say "that's when accidents happen." Projects started early, at 7 AM, to count tongue flicks of Western Diamondback Rattlesnakes toward scent cues, followed by explanations of the behaviors of pit vipers, vomeronasal chemoreception, trail following and many other topics in herpetology and predatory behaviors of rattlesnakes. Of course, there was always a quick lesson on statistics—Dave loved statistics. My fascination grew, and as simple questions quickly progressed into 100s, I soon entertained the idea of pursuing a graduate degree working under Dave's guidance.

Shortly after I was accepted into the Master's program working with Dave to examine chemoreception in snakes, he was diagnosed with cancer. In response to strict orders by his doctors to avoid reptiles, especially venomous snakes, and countless visits to oncologist and chemotherapy sessions, resulted in him spending the vast majority of his time away from his lab. "Don't worry," he would always tell me "everything will work out just fine." Frequent emails and monthly visits to his house to discuss new research ideas, analyze data, work on statistics, and to write manuscripts together slowly progressed into weekly visits just to talk, to have lunch or dinner with him and his family, to discuss the struggles of graduate school and my future goals and plans. Visits were no longer solely for professional discussions; they were also to spend time with a guy that was becoming one of my closest friends. Dave would share stories of spending late nights in the lab— "I would take naps on a cot I had in my office, and then wake up and count tongue flicks throughout the night. Amazing what you can do with all that free time." And concerning the one and only time he was envenomated, by a Lower California Rattlesnake (*Crotalus enyo*), he simply said: "I was rushing." Publications over his 35-year career almost always had a unique twist or funny story attached, such as sticking a mouse carcass into a condom to examine strike-induced chemosensory searching behaviors when the snake's palate doesn't come in contact with the prey's integument. I could only imagine the look on my face as he explained to me his reasoning for shoving a dead mouse into a condom. Through all of these visits, I got to know Dave as someone beyond my academic advisor. He had become one of my best friends, and with every story or problem I shared with him, or request for guidance that I needed, he always listened, always offered a solution, and always extended the most sincere advice.

As I met more herpetologists, psychologists, and biologists who knew Dave, the one thing I heard repeatedly is how he so selflessly, during critical times, helped with aspects of their project(s) or even with their career. One of the first herpetology talks I heard years ago ended with the typical slide of acknowledgments to everyone that had assisted with the project. However, on the next slide was a large picture of Dave cautiously looking at a Brown Tree Snake in his lab, as Dr. Steve Mackessy said, "Dave has so generously helped me with my career, I really just want to say thank you to him." I recently spoke with Dr. Thomas Dunn, also at the University of Northern Colorado, and we both agreed that there must be at least 100 more of us out there that Dave had so generously helped. Dave was one of the most modest people I have ever met, always willing to help, and although his lab has provided some of the most significant contributions to rattlesnake biology and behavior to date, he never talked about himself. In spite of his modesty, his work with rattlesnake behavior was novel and inspirational, helping to transform public opinion of these maligned and magnificent animals. As I now pursue my PhD, I always think of the talk I heard years ago, and how now, for myself, Dave provided the foundation for the career I always dreamed of. He believed in me when so many would have just looked at my poor grades and GRE scores and would have turned away. He listened and provided insights to every crazy research project I came up with. He continued helping me with my research, writing, and statistics, and even during the continuous chemotherapy treatments, visits to the oncologist and weekly stays in the hospital, he never once hesitated to be there for me during a time of need, right up to the end. Dave lost his long fight with cancer just after the New Year—herpetology and behavioral sciences have lost an honest, compassionate scientist, and I lost an academic mentor, and more importantly, a true friend and colleague.

Anthony Saviola
University of Northern Colorado

***

Although it took me a considerable time to realize it, Dave Chiszar's interests were closely aligned with my own, and our paths brought us surprisingly close to one another, either geographically or professionally. Those paths were never closer in space than at the University of Colorado, where I was halfway through my undergraduate degree when Dave arrived in 1970. Unfortunately, as a student obsessed with the systematics and morphology of snakes, ophidian behavior was an afterthought for me, and I was unaware of Dave's arrival at CU. His appointment in the Department of Psychology, rather than one of the several biology departments, only served to deepen the chasm between the new Assistant Professor and the undergraduate biology student.

By the time Dave published his first paper on ophidian behavior, in 1975, I was in graduate school at the University of Kansas, still working on systematics and morphology. That same year Dave began to publish with Hobart Smith, who had been my undergraduate mentor, and it was largely through Hobart's publications that I began to follow Dave's growing herpetological output. Dave was beginning to work at a number of major zoos, a move that would soon broaden his taxonomic range and propel him into a period of accelerating studies on predatory behavior and

the role of the vomeronasal sense in snakes. In 1980 Dave published his first paper on strike-induced chemosensory searching (SICS) in rattlesnakes, demonstrating the critical role that the strike plays in releasing prey-searching behavior in pitvipers.

I was following Dave's work on SICS as I began to work on the embryonic development of the pit organs, a project that involved bringing numbers of gravid female pitvipers into the lab for collection of embryos. As my live collection grew during the 1980s, Dave's observations on the role of the strike in initiating the feeding sequence revealed its practical side, as I learned that recalcitrant captive pitvipers could be induced to feed by harassing them into a defensive strike at their prey. Another of Dave's discoveries—that too-frequent cage-cleaning can induce repeated defecation and loss of nutrients in captive snakes—proved invaluable in convincing my Institutional Animal Care and Use Committee that snakes were healthier when cages were not cleaned obsessively.

Our paths crossed only a few times at conferences, but when they did Dave was always a jovial presence and a delightful companion at dinners and socials. I can never remember a time when he didn't have a broad smile on his face, and his presentations were filled with the joy he brought to his science and to life in general. I'll remember Dave most for the delight he took in his interactions with colleagues and for the critical role that he played in revealing fundamental elements of the feeding and foraging behaviors of snakes.

SSAR TO MEET IN 2015 AT UNIVERSITY OF KANSAS

On the campus of one of the world's major herpetological research centers

JULY 30 TO AUGUST 3, 2015

The SSAR held highly successful meetings at KU in 1977 and 1996, and anticipates another memorable event in 2015. The intimate campus setting will facilitate personal interaction, while moderating fees for registration and lodging. The meeting will be co-sponsored by PARC (Partners in Amphibian and Reptile Conservation) and the Kansas Herpetological Society.

Featured events will include:

- Oral presentations and poster sessions
- Featured symposia (to be announced)
- Selected plenary speakers (to be announced)
- Recognition of senior herpetologists
- Commercial and non-commercial display booths
- Tours of the Henry Fitch Natural History Reserve
- Tours of newly renovated research laboratories
- New audio/visual shows
- Live Kansas herps for photography
- Silent and live auctions

Hosted by: The University of Kansas Biodiversity Institute and Museum of Natural History.

Local committee: Rafe Brown, William Duellman, Rich Glor, Linda Trueb, Andrew Campbell, and George Pisani.

Deadly Encounters by and upon Crocodilians Depicted in Historical Illustrations and Accounts. Part I. Assaults by Crocodilians

> The old adage "eternal vigilance is the price of safety" was never more true than for those living near the haunts of the estuarine crocodile. One does not have to enter the water to provide a meal for these great reptiles as they lie concealed in the muddy waters of lagoon or river. Often the first intimation of their presence received by some unwary stroller at the water's edge is when, his legs swept suddenly from beneath him by a deftly wielded tail, he is seized in a vise-like grip of great jaws to disappear in swirling water whose surface quickly resumes its normal placid appearance regardless of the human tragedy it conceals.—Arthur Loveridge (1945)

> A number of the bigger crocodilians are perversely unable to see the special nature of the human animal, and absentmindedly eat him from time to time.—Archie Carr (1970)

> Such is the average crocodile—an active, vicious and, above all, treacherous brute. When the keepers of the reptile house in the New York Zoological Park clean out the big pool for crocodilians, they actually walk over the backs of some of the big 'gators, so tame are these. They never become unduly familiar with the crocodiles, finding it necessary to pen the latter behind heavy barred gates—and in the process the men are often chased from the enclosure.—Raymond L. Ditmars (1933)

The ongoing struggle that crocodilians face, both as predators and prey, is beautifully documented in historical images and written accounts. In this paper, I show how humans have dealt with these reptiles, mostly catastrophically for the latter, over many centuries. First, humans are at risk because crocodilians can eat them and so the literature is filled with arresting images and graphic descriptions of attacks upon man. Second, crocodilians are efficient predators so humans are intrigued and often unnerved by their ability to subdue a plethora of prey, ranging in size from small invertebrates to large mammals. Watching a large crocodilian feed on sizable prey is an unforgettable experience—zoo patrons flock to an exhibit whenever dead rabbits are offered as food and stand slack-jawed and mesmerized during the entire banquet. Third, many predators find a small crocodile or alligator to be a tasty meal and cannibalism is not an unusual occurrence. Fourth, the crocodilian skin is highly prized in the fashion industry so many taxa are currently at risk in the wild. Others are being threatened by habitat alteration: especially Philippine Crocodiles (less than 100), Chinese Alligators (estimated at 300), and Siamese Crocodiles (virtually extinct) as well as Gharials, and Mugger, Cuban, Morelet's, and Orinoco Crocodiles to name a few. As a result, an alarming number of crocodilians are listed as threatened and endangered. To supply the insatiable demand for leather, crocodile farming has become a big business and illegal trading still exists in spite of nominal protection (Brazaitis and Watkins-Colwell 2011). The sum total of these pressures: Crocodilians are generally in trouble where they are found and the situation is not likely to markedly improve.

If given half a chance, crocodilians are adept at survival. A Saltwater Crocodile between 6–7 feet escaped into the zoo lake in the Menagerie at the Botanic Gardens in Singapore in the early 1900s and began eating waterfowl and stalking laborers. Many attempts to kill it failed: it was shot twice, arsenic and strychnine were put into chickens, dynamite was tried. The lake was virtually drained— with shots and spears aimed at the crocodile— but it buried into the mud and escaped that night (Ridley 1906).

Major Stanley Smyth Flower (1925) observed the following: "Crocodilians may perhaps live to a great age: probably longer in the sheltered conditions of captivity than when exposed to the active, combatant, competitive career that is theirs in nature." He listed longevities as follows: American Alligator–40 years and perhaps longer than 73 but record cannot be verified with certainty; Mugger Crocodile–31 years and still alive; Nile Crocodile–17 years and still alive; African Dwarf and Slender-snouted Crocodiles–15 years; Cuban Crocodile–13 years; and American Crocodile–10 years. Snider and Bowler (1992) listed the following records in North American collections: American Alligator >73 years; Chinese Alligator >46 years; six caiman taxa between 15–30 years; 14 crocodile taxa between 3–50 years, and Gharial >27 years.

Peter Brazaitis (pers. comm.) describes the predatory behavior and intelligence of crocodilians:

> "The first is that there is considerable difference between the way an alligator (or possibly expanded to "alligatorids"), zeroes in on potential prey or invader. Alligators seem to be attracted to something and then often swim toward it, mostly on the surface, perhaps pausing from time to time along the way, perhaps to evaluate the purpose of the target, eventually getting close enough to lunge in an attack. There is no hard set of rules. Crocodiles, on the other hand, often detect prey or an invader, slip into the water without so much as creating a ripple, and travel in the direction of the invader or prey underwater, coming to the surface from time to time to relocate and get their bearings. Eventually they are within lunging distance, perhaps surfacing at the end of the stalk with the head at the surface, well camouflaged by floating debris. At this time the prey/

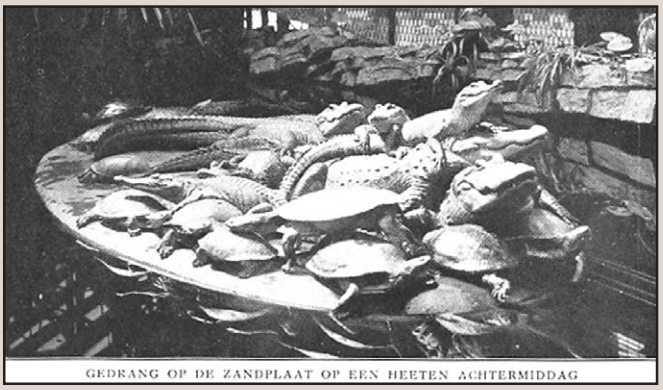
person still has had no idea that a crocodile is about to get them. Escape is virtually not possible. Dr. Richard Root, who was taken by a Nile croc out of his canoe in Botswana a couple of years ago, was taken and disappeared beneath the water in an instant, never to be seen again, before the people and his wife in a following canoe even knew there was a crocodile present. His colleagues here called me in disbelief and asked if such a thing could happen? Undoubtedly the croc had been successful in easily plucking people out of shallow draft canoes before. Crocs learn people behaviors and modify their own behaviors accordingly.

At AZA Croc school this year we had a student, 'Peter,' from the wildlife service in Uganda. He told me one night that Nile crocs were probably taking upwards of 500 people throughout the country a year. He said that in his district the local lake had been depleted of fish by overfishing. The crocodiles had learned that when they hear the people come down to the lake with nets and baskets and start fishing, they will have fish. The crocodiles then come from wherever they are and take the fish. Absent the fish they take the people.

I recall how I used to exit the crocodile pool at the Reptile house [Wildlife Conservation Society, Bronx Zoo] when we had a pair of young 6–7 foot long Nile crocs in the pool with several mixed species. The two worked cooperatively every time I entered the exhibit and began to leave. There was a bit of a shallow inlet, about 3-feet wide, immediately in front of the exit gate. I had to hop over it to get to the gate. The pair would split. One croc would swim underwater to one end of the pool and come around the backside of a support column that rose out of the pool to one side, and sit waiting underwater along my path for me to arrive. The other croc would swim underwater and lay at the bottom of the inlet and wait for me to arrive and start to hop over the inlet. My shadow on the water above the croc was the trigger. Then both would lunge, bursting from beneath the water at the last moment. Once I learned the plan, and as I always carried a stiff, brown-fiber broom with me in the pool, I could prematurely trigger the attack by reaching ahead and touching the surface of the water with the broom above the nearest lurking croc. Triggering one was usually sufficient to trigger the second. Once the "attack" was fruitlessly expended, the crocs would forget the whole thing and give up the sham."

Operant conditioning is modifying behavior through positive or negative reinforcement. Large captive crocodilians can be dangerous to zoo workers performing basic husbandry or medical procedures. For greater safety, especially while feeding or shifting these reptiles, operant conditioning is being used routinely in a number of zoos. Initially, a whistle is used as a bridge to reinforce a desired behavior, conditioning the animal to associate the sound with food. Next, the crocodilian must target a colored disk attached to a pole, touching its snout to it without moving or biting; when this stationing behavior is performed properly, it is fed. There are several excellent articles on training crocodilians using this method: Augustine (2009, 2010), Augustine and Baumer (2012), and Hellmuth et al. (2012).

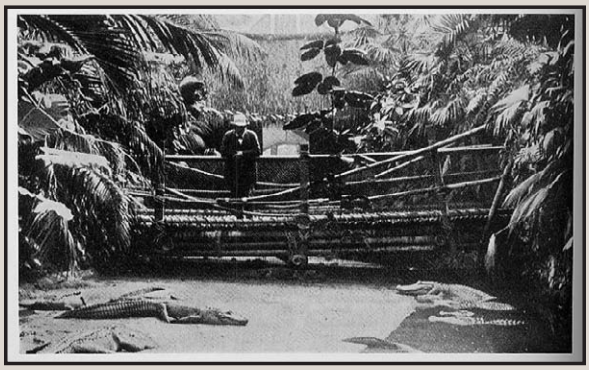
The earliest record reflecting crocodiles in captivity is from the pictographs and hieroglyphs of 2500 BC, found at the Saqqara cemetery near Memphis in Egypt. Two Romans, Aemilius Scaurus, built a tank filled with water for his five crocodiles in 58 BC and the 3rd century Roman emperor Heliogabalus (= Elagabalus) kept one of these reptiles in his palace; it was said to be tractable. "The Emperor Augustus had the Flavinian circus filled with water, and exhibited there to the people thirty-six crocodiles, which were killed by an equal number of men, who were habituated to fight with these animals" (Cuvier 1831).



Crocodilians were kept in temple precincts in ancient Oriental societies. Guggisberg (1972) noted that Egyptian priests in the 3rd millennium held "sacred crocodile feedings." Alligators were religious symbols in China, and the Arabs and Turks maintained crocodiles. Gavials were held in the menageries of Buddhist convents in Burma and Siam. In 1882, the Trivandrum Zoo in India had four Mugger Crocodiles on exhibit. A Mugger Crocodile was living at the Adelaide Zoological Gardens in Australia in 1886.

In Europe during the Renaissance, crocodiles were kept in menageries by Italian princes and held at the Royal Menagerie of Louis IV at Versailles, France as early as 1664; the arrival of a crocodile at the Vineuil Menagerie in 1783 caused much public interest. At the Jardin des Plantes in Paris in 1852, six American Alligators were on display where they lived for many years (Duméril 1854–1855, 1858–1861).

In the Tower Menagerie in London, the American Alligator (*Crocodilus Lucius*, now *Alligator mississippiensis*) was described by E. T. Bennett (1829) in *The Tower Menagerie*. There is also a picture in Robert Huish's *The Wonders of the Animal Kingdom Exhibiting Delineations of the Most Distinguished Wild Animals in the Various Menageries of the Country* in 1830 (see Murphy 2006). In 1872 at the London Zoo, the collection included the Nile, Cuban, Slender-snouted, Mugger, and American crocodiles, as well as the Yacare Caiman and American Alligator (Sclater 1872). C. J. Cornish (1894) described African Slender-snouted, American, Nile, Estuarine, Cuban, and West African Dwarf crocodiles, as well as the Dwarf, Spectacled, and Broad-nosed caiman living in the reptile building. The collection also included American and Chinese Alligators.



In 1821, the Menagerie in the Imperial Hofburg [Castle] Garden in Vienna, exhibited an American Crocodile. Crocodilians were displayed in the Promenade at the zoological gardens (Jardin Zoologique d'Anvers) in Antwerp, Belgium (Gens 1861). At the Reptile House in the Royal Zoological Gardens in Amsterdam in 1907, an African Slender-snouted Crocodile and alligators were on exhibit. At the Rotterdam Zoo, known now also as Diergaarde Blijdorp, a list of taxa included the False Gavial, Nile Crocodile, and several American Alligators in 1858 (Visser 2003). A new reptile building was built in May 1906. During World War II bombing raids, survivors included a pair of American Alligators and African Slender-Snouted Crocodiles. The Berlin Zoo had eight species between 1860–1875; Oskar Heinroth designed the first walk-through "Crocodile Hall" in 1913 in the new Aquarium. The onlooker seems to be awfully close to the reptiles. I certainly would not get that near an adult Cuban or Philippine crocodile, two of the most agile and aggressive species.

The first book on herpetoculture in English was the Reverend Gregory Climenson Bateman's *The Vivarium*, published in 1897.

Berlin Aquarium Crocodile Hall in 1914.

There were many advertisements for animals, plants, and supplies in his book. According to Bateman, a broad range of live reptiles and amphibians were obtainable in London in 1897. In addition to the common European species, a number of rare, exotic types were offered for sale, including young American Alligators and crocodiles. Bateman continues, "My Alligator unfortunately, lost his temper when a friend and I one day were trying to photograph him, and, as I was holding him, he whipped my legs with his tail in such a way that I suffered pain from the blows for some little time afterwards, and thought there was some truth in the saying, 'If you want to offend your friend, photograph him.'"

Thousands of caimans and small American Alligators and crocodiles were imported into the U.S. and Europe for the pet trade during the twentieth century and most were kept in deplorable conditions. There was a publication connected to Ross Allen by Dick Bothwell called *The Great Outdoors Book of Alligators* in 1962. It has a chapter entitled "Crocodilian As a Pet" in which it was said that G. L. Thompson of Lane Wilson Company in Monroe, Louisiana shipped 500 caimans a week to pet shops and variety stores in the US. An aspiring pet keeper could order one through the mail and the poor dehydrated creature would arrive in a small cardboard box, similar to those used to ship baby turtles. Books encouraging the keeping of them in captivity were available (Roberts 1958; Schneider, n.d.)

Frank Buckland in *Notes and Jottings from Animal Life* in 1882 published this weird observation: "Several of the ladies in Southport have purchased pets among them, and it may be that no Southport lady will consider her establishment perfect without a baby alligator to bask on the hearth rug, and go out on a walk on the promenade with her. When the pet defuncts, he can be stuffed, gilt, and put in the hat for an ornament, don't you know?" As those few that survived captivity grew to predictable adult size, zoo workers were inundated with telephone calls from desperate owners pleading to take an aggressive crocodilian off their hands.

In the 16th century, crocodilians were drawn from antique statues, medals, and coins. Sometimes sketched by travelers, crocodilians were often shown with tails curling around and upwards behind the rest of the body, perhaps due to a need to fit the long shape on a round coin. An interesting example is "Cocodrillus," from the *Hortus sanitatis* in 1497.

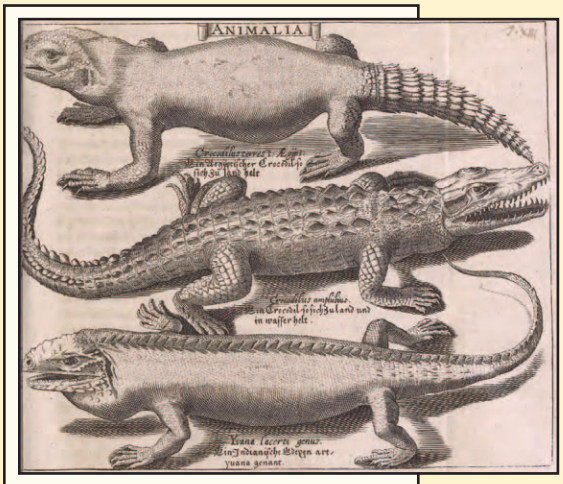
Many of the early depictions of crocodilians from the New World looked like lizards as there was confusion as to what constituted an "iguana" or a "crocodile;" some writers considered iguanas to be the same animal as the Nile Crocodile. For example, Francisco Fernandez de Oviedo "...begins by criticizing Martyr's assertion that the iguanas are identical to the crocodilians of the Nile on the grounds of the obvious size different size of the animals, a fact evident to all those who have seen them. Oviedo then quotes Isidore of Seville's Etymologies on the crocodile and concludes that the iguana could never be a crocodile because, as Isidore says, these are large animals and usually of a yellow colour...while the iguanas measure about four feet and are green or brownish. Besides, Isidore holds that the crocodile is the only animal which elevates the upper maxillary, something the iguanas are unable to do." (quote from Miguel de Asúa and Roger French, 2005. *A New World of Animals. Early Modern Europeans on the Creatures of Iberian America*). The idea that the crocodile's "upper jaw" was hinged also shows up in a lot of illustrations.

During the late 1500s–1700, some authors were compilers rather than scientists, and illustrations were sometimes copied from earlier publications. Mistakes contained in the original illustrations were perpetuated in later reproductions, as shown in the publication by Simmons and Snider (2012). Examples are shown here, arranged mostly chronologically, of scientific endeavor and artistic expression by using changing techniques and methods: woodcuts, etchings and copper engravings, and lithographs. Peter Brazaitis (pers. comm.), who published a key to living crocodilians in 1973, noticed the following: "As an aside, in looking at the illustrations, I found that in a number of cases the artist's eye had captured specific relatively obscure characteristics that discriminated specific species. Like the pre-orbital ridges on the snout of *Crocodylus porosus*; the missing scales in the dorsal scalation and the pre-orbital hump of *C. acutus*; the diagonal dark bar across the anterior flank of *C. niloticus*; the diagonal bony elevations on the snout and the tan dorsal neck of *Melanosuchus niger*, etc. Wonderful!"

Caricatures of crocodilians even appear in cartoons as evil creatures placing humans at risk. In an issue of *Harper's Weekly* (1871) by political cartoonist Thomas Nast, Catholic bishops in the shape of alligators are emerging from the water to threaten the American family (and the American public school), standing horrified at the water's edge. The bishops are wearing miters, tall pointed hats with peaks in front and back, festooned with teeth inside to look like crocodilian jaws. This cartoon is called "The American River Ganges." St. Peter's Catholic Cathedral is in the background.

With most of the legends in my articles, appropriate literature quotations are included to put the images in context. Part II, showing assaults upon crocodilians plus literature citations for both installments, will appear in the next issue.

This 16th century German etching vividly sums up the challenges in the crocodilian world as both predators and prey.



COURTESY OF DEN HAAG, MUSEUM MEERMANNO WESTREENIANUM, [SHELF LOCATION] 10 B 25, 12R

An array of deadly encounters may be found in Medieval Bestiaries between crocodilians and men with the former clearly having the upper hand. Notice that humans are swallowed whole. After dinner is finished, it is said that the crocodile will weep for the rest of its life in repentance! The expression "Crocodile Tears" appeared in bestiaries and are a false or insincere display of emotion such as a hypocrite crying fake tears of grief. It stemmed from the belief that crocodiles weep in order to lure their prey, or that they cry for the victims they are eating. Although "tears" will be visible after a crocodile is out of the water for long periods and the eyes begin to dry out, they do not actually cry. Crocodiles possess lacrymal glands that secrete a proteinaceous fluid behind the nictitating membrane to prevent dessication, so ancients believed that "tears" were generated as in humans. It is striking that this expression is still in use.

Artists during this era likely did not have access to living or preserved crocodilians so the renditions were highly stylized. In early drawings, these carnivorous reptiles are shown with impressive dentition. Illustration of Cocodrillus from the *Hortus sanitatis* in 1497.

COURTESY OF SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON, DC.

Naturalistic drawing from *Rariora musei Besleriana* by Basilius Besler in 1500s. Bartholomaeus (or Bartholomeus) Anglicus, or Bartholomew the Englishman, was a Franciscan monk of the thirteenth century who had a vivid imagination while describing the crocodile. He wrote his encyclopedia, *De proprietatibus rerum* Book 18 (On the nature of things, or On the properties of things), some time before 1260: "If the crocodile findeth a man by the brim of the water, or by the cliff, he slayeth him if he may, and then he weepeth upon him, and swalloweth him at the last."

Illustration of crocodile in *Senensis medici, Commentarii in sex libros Pedacii Dioscoridis Anazarbei De medica materia. . .* by Petri Andreæ Matthioli in 1565. "As it lives chiefly in the river, it has the inside of its mouth constantly covered with leeches; hence it happens that, while all the other birds and beasts avoid it, with the trochilus it lives at peace, since it owes much to that bird: for the crocodile, when he leaves the water and comes out upon the land, is in the habit of lying with his mouth wide open, facing the western breeze: at such times the trochilus goes into his mouth and devours the leeches. This benefits the crocodile, who is pleased, and takes care not to hurt the trochilus."—Herodotus (*History*, book 2)

COPYRIGHT BY THE NATURAL HISTORY MUSEUM, LONDON

This image is often improperly cited across the internet. The alligator image is actually a famous drawing (not a published print) from a manuscript collection by William Bartram called the "Fothergill Album," so named after John Fothergill, an 18th century British physician who was Bartram's expedition patron. After Fothergill's death, the collection was sold. Sir Joseph Banks purchased many of the specimens and their related materials including the album, which eventually became the property of the British Natural History Museum. The Fothergill album was reproduced in 1968 in the Memoirs of the American Philosophical Society (v. 74) by the title *William Bartram: Botanical and Zoological Drawings, 1756-1788*. It is from this publication that likely most of the published images come. Bartram (1794) wrote in *Travels*… regarding "The Alegator of St John [River, East Florida]," "…represents the action of this terrible monster when they bellow in the Spring Season. They force the water out of their throat which falls from their mouth like a Cataract & a stream or vapour from their Nostrils like smoke."

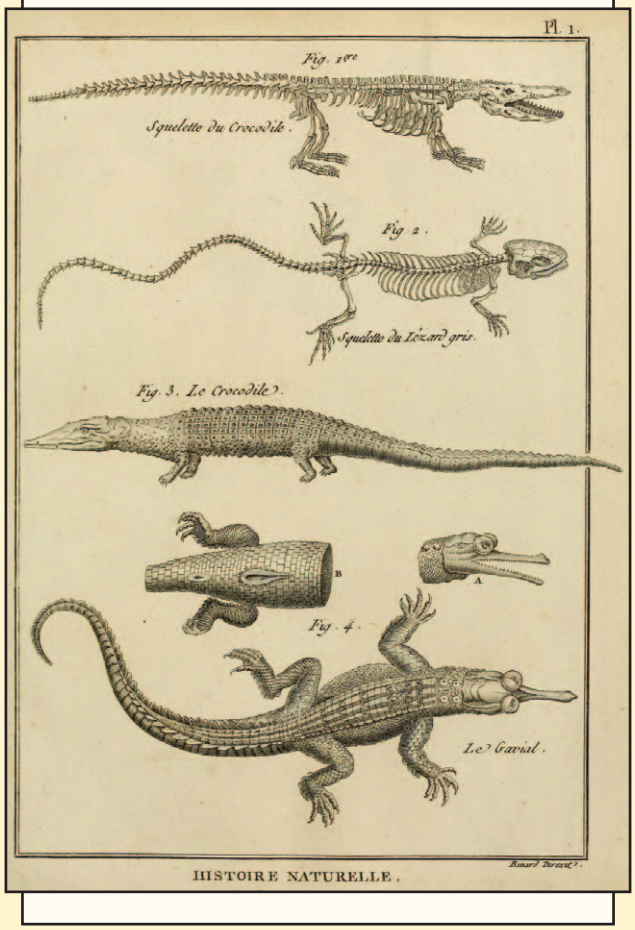
Illustration from *The Zoological Miscellany: Being Descriptions of New, or Interesting Animals / / by William Elford Leach* (1814)… "Human beings have a great dread of this voracious reptile. Many instances are known where men have been surprised near the water's edge or captured when they have fallen into the river. There is, it is said, only one way of escape from the jaws of the Crocodile, and that is to turn boldly upon the scaly foe and press the thumbs into his eyes, so as to force him to relax his hold or relinquish the pursuit."—J. G. Wood (1885), *Popular Natural History*

COURTESY OF SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON, DC



Species of Crocodile Called "Alligator" in *Histoire Générale des Voyages* in 1739. "When an alligator catches a large animal that is too large to be killed by crushing it in its jaws, it immediately starts rolling. The roll is accomplished by throwing its tail up and sidewise and turning its body at the same time and in the same direction that it twists its tail, holding its feet folded backwards against its sides; this twisting and rolling is done with great power, and the animal grasped in its jaws is violently thrashed about until it is quite dead. If an alligator catches an animal that is too large to be swallowed whole, it crushes the leg bones close to the body in its powerful jaws, and then by twisting, rolling and shaking, tears the member loose from the body when it can by easily swallowed. It is generally supposed alligators will not swallow food under the water; this is a mistake, however, as I have often seen alligators catch birds, fish and small animals and sink with them, swallowing the food while under the water. My observations are that an alligator can and will swallow while under water, food small enough to be swallowed without opening its mouth. If the food must be chewed, which necessitates opening its jaws, the head is always raised above the water. I have, on numerous occasions, when fishing on the bottom for large saltwater fish, using large baits, either fish or crab, had alligators swallow bait and hook, and for a few minutes they put up a hard fight when hooked on a fish line. That alligators sometimes hunt their food on the bottom of streams and ponds has been proven to me by seeing alligators that had not before been in view, rise to the surface with large water snakes, turtles or crabs in their mouths, which were killed and swallowed above the water's surface."— Edward Avery McIlhenny (1935), *The Alligator's Life History…*

Illustration of crocodile with a bunch of slender teeth of the same size and strange eyes in *Locupletissimi rerum naturalium thesauri* by Albertus Seba in 1734–1765. Crocodilians have four digits on the hind foot. "Even the smallest children seem to recognize very early in life that crocodiles are animals that bite. Not long after that, they learn that crocodiles will not only bite—like the neighbourhood dogs with which they are familiar—but they can also eat you. It must surely both confuse and excite children within a world so heavily shaped by 'safety.' How can there be any large predators left that attack and eat people? Why haven't parents got rid of such troublesome 'things.' The image of crocodiles is akin to that of a very clever and exciting criminal, that is too smart, cunning, sly or deceptive to be 'got rid of.' The aura of romanticism that surrounds some not-so-pleasant people (Robin Hood, Billy the Kid, Ned Kelly, Bonnie and Clyde) is similar to that placed on large predatory animals by children."—Grahame Webb & Charlie Manolis (1998), *Australian Crocodiles.*

Illustration in Pierre Joseph Bonnaterre, abbé (1789) *Tableau encyclopédique et méthodique des trois règnes de la nature…* "Its usual method is to float along upon the surface, and seize whatever animals come within its reach; but when this method fails, it then goes closer to the bank. Disappointed of its fishy prey, it there waits, covered up among the sedges, in patient expectation of some land animal that may come to drink; the dog, the bull, the tiger, or man himself. Nothing is to be seen of the insidious destroyer as the animal approaches; nor is its retreat discovered till it be too late for safety. It seizes the victim with a spring, and goes at a bound much faster than so unwieldy an animal could be thought capable of; then, having secured the creature with both teeth and claws, it drags it into the water, instantly sinks with it to the bottom, and in this manner quickly drowns it."—*A System of Natural History*, 1834

Illustration of American Alligator from Antoine Simon Le Page du Pratz (1758) *Histoire de la Louisiane…* Michael G. Frick showed photographs to me where alligators were regularly traveling to marine environments where they preyed upon sea turtles, sharks, stingrays, and other organisms. Courtesy of Smithsonian Institution Libraries, Washington, DC "The Common Alligator inhabits Northern America, and is plentifully found in the Mississippi, the lakes and rivers of Louisiana and Carolina, and similar localities. It is a fierce and dangerous reptile, in many of its habits bearing a close resemblance to the crocodiles and the other members of the family. Unlike the crocodile, however, it avoids the salt water, and is but seldom seen even near the mouths of rivers, where the tide gives a brackish taste to their waters. It is mostly a fish-eater, haunting those portions of the rivers where its prey most abounds, and catching them by diving under a passing shoal, snapping up one or two victims as it passes through them, tossing them in the air for the purpose of ejecting the water which has necessarily filled its mouth, catching them adroitly as they fall, and then swallowing them."—J. G. Wood (1885), *Popular Natural History*

Crocodile eyeing a potential meal. Feet have four talons like a bird of prey but the digits are reversed. Illustration from André Thevet (1556) *Cosmographie de Levant…* "This croc, which measured 12 feet from tip of tail to tip of snout, must have had a catholic taste in its form of diet. On opening up the stomach we found a strange assortment of articles—sticks, about a dozen round and smooth pebbles, an African woman's foot, an African man's hand, some coloured beads, wire bangles and anklets, a waterbuck's hoof, the claws of a cheetah, a shinbone of a reedbuck, the shell plates of a large river turtle, the horns of a goat, the hoof of a calf, and a variety of other strange objects. I felt delighted at having been its executioner."—A. D. Graham (1973), *Eyelids of Morning; The Mingled Destinies of Crocodiles and Men*

"The Crocodile, so remarkable for its size and powers of destruction, has in all ages been regarded as one of the most formidable animals of the warmer regions. It is a native of Asia and Africa, but seems to be most common in the latter; inhabiting large rivers, as the Nile, the Niger, &c. and preying principally on fish, but occasionally seizing on almost every animal which happens to be exposed to its rapacity. …In the full grown animal it is so strong and thick as easily to repel a musket-ball …The Crocodile, in a young state, is by no means to be dreaded, its small size and weakness preventing it from being able to injure any of the larger animals: it, therefore, contents itself with fish and other small prey... but in the glowing regions of Africa, where it arrives at its full strength and power, it is justly regarded as the most formidable in habitant of the rivers. It lies in wait near the banks, and snatches dogs and other animals, swallowing them instantly, and then plunging into the flood, and seeking some retired part, where it may lie concealed till hunger again invites it to its prey."—George Shaw (1982), *General Zoology…*

Illustration from Constant Duméril et al. (1834–1854), *Erpétologie générale, ou, Histoire naturelle complète des reptiles / / par A.M.C. Duméril et par G. Bibron.* "[Raymond L.] Ditmars thus describes the fate of a dog that approached too near a very large alligator: 'As a dog, weighing about fifty pounds, unwarily approached the edge of this creature's tank, it was suddenly grasped and before completing its first yelp of terror was dragged beneath the surface. A few minutes later the twelve-foot saurian appeared at the top, holding the dead canine in its jaws. The dog was shifted about, amid the sound of breaking bones, and swallowed head first, and entire, after a few gulps."—Albert Moore Reese (1915), *The Alligator and its Allies*

Illustration from *Dictionnaire universel d'histoire naturelle, zoologie, atlas. Reptiles, Poissons et Insectes, tome deuxiéme,* by M. Charles D'Orbigny in 1849. "All crocodilians are predators that overpower their prey within seconds. The attack can happen in the water, underwater, from the water onto the land or land into water, and also by jumping into the air."—Ludwig Trutnau and Ralf Sommerlad (2006), *Crocodilians: Their Natural History & Captive Husbandry*

COURTESY OF SMITHSONIAN INSTITUTION LIBRARIES, WASHINGTON, DC

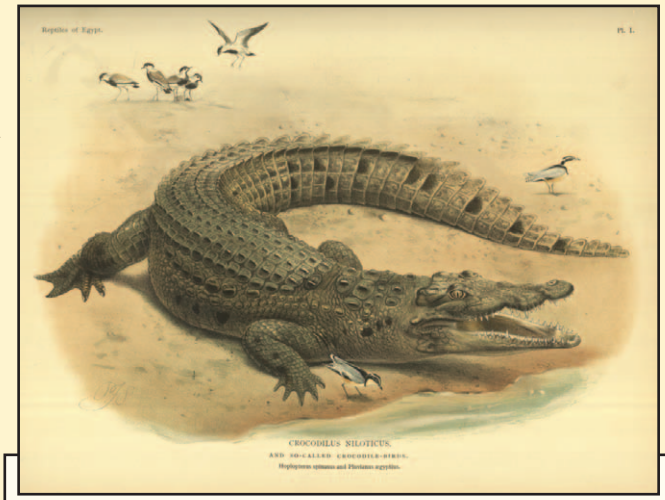

Illustration in W. F. Kirby's English adaptation of Gotthilf Heinrich von Schubert's *Naturgeschichte des Thierreichs…,* published in 1869. The author says that the Nile Crocodile (top) reaches a length of 20–30 feet, lives to be at least 100 years old, has eggs as big as goose eggs, and young hatch in one month and are two feet long. Bullets bounce off its back. It is very fierce and feeds on sheep, antelope and humans. The mongoose is the predator of its eggs and young. The Mississippi Alligator below is common and is dangerous, attacking boats on rivers. In this illustration, although somewhat unclear, it appears as though one of these crocodilians may be transporting young in the mouth, next to a group of eggs. Notice the predation event in the upper left-hand corner.

There are beautiful plates in Alfred E. Brehm's *Les Merveilles de la Nature. Les Reptiles et les Batraciens* (Librairie J.-B. Baillière et Fils, Paris, 1883). Brehm was Director of the Hamburg Zoo in Germany from 1863 onward and founder of the Aquarium Unter den Linden (Berlin's main street) in 1869. This drawing is of a Gharial (*Gavialis gengeticus*). "Although possessing the reputation of being more or less harmless, the stomach of a recently dissected specimen was found to contain human remains, a fact proving beyond all possible doubt that large specimens, at least, will not hesitate to attack man when hungry. Two seven-foot-long specimens that have come under my charge at the Zoological Gardens were extremely savage. On arrival both these specimens refused all food, and it was not until they had been over three months in captivity that they took their first meal. The fish are caught by the tip of the snout, by means of a rapid sideway snap, and are passed down to the mouth, head first, in a series of jerks."—Edward G. Boulenger (1914), *Reptiles and Batrachians*

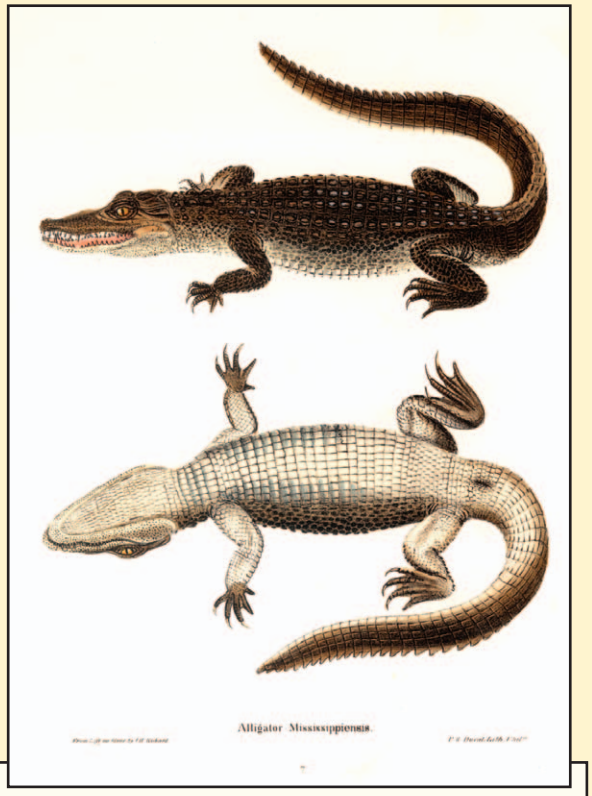

Illustration from George Shaw's *The naturalists' miscellany…*in 1789–1813 (reproduced in Haines, *Slithy Toves,* SSAR 2000).

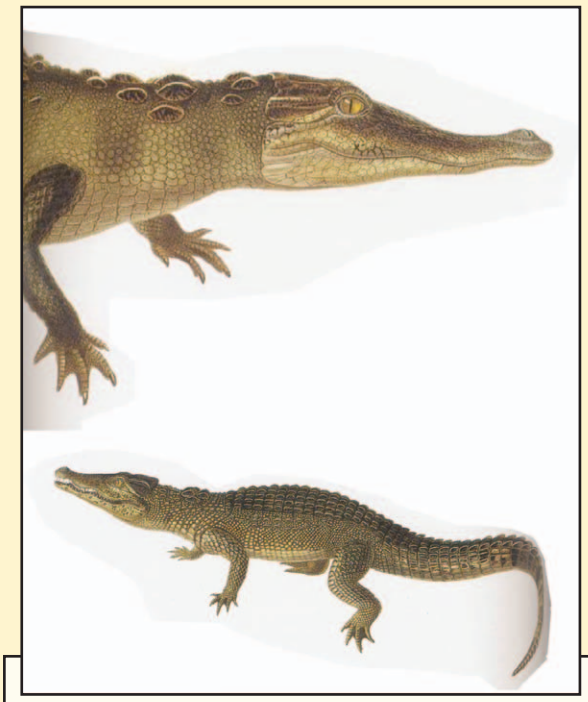
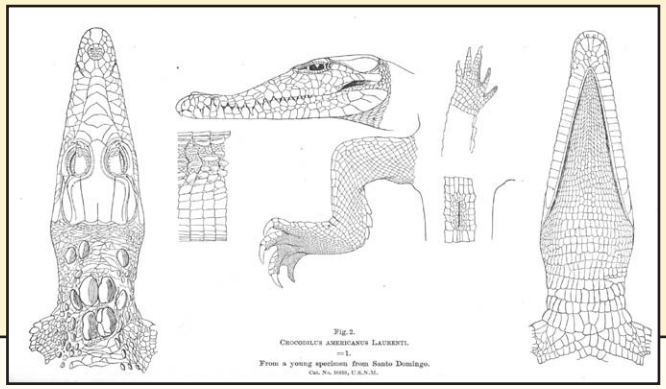
COLLECTIONS (ARCHIVES) OF THE ERNST MAYR LIBRARY OF THE MUSEUM COMPARATIVE ZOOLOGY, HARVARD UNIVERSITY

This beautiful image may be one of the best crocodilian portraits ever rendered. Notice the Crocodile Birds. "The Nile crocodile has always and justly been credited with great ferocity, but the degree to which it manifests this seems to depend largely on the abundance of its food-supply, as pointed out by Maçoudi and by Schweinfurth. Fish is its principal diet, but birds, the domestic animals found along the banks of the Nile, baboons, and man himself, all fall to it as prey. It either seizes its prey directly with its jaws or, by means of its powerful tail, whisks its prey within reach of them, dragging it under the water."—John Anderson (1898), *Zoology of Egypt*

COLLECTIONS (ARCHIVES) OF THE ERNST MAYR LIBRARY OF THE MUSEUM COMPARATIVE ZOOLOGY, HARVARD UNIVERSITY

John Edwards Holbrook published *North American Herpetology*, beginning in 1836, covering all herps found east of the Mississippi River at that time. "The Alligator in his native state is exceedingly voracious, and feeds on any animal substance that may fall in his way; though he seems most attracted by fish, and by other animals in motion, as minks, musk-rats, dogs, &c., so as to render it almost impossible for them to cross even small streams without danger, at certain seasons of the year. These the Alligator seizes, drags under water, suffocates, and conveys to his lair, to be devoured at leisure."—Holbrook (1836)





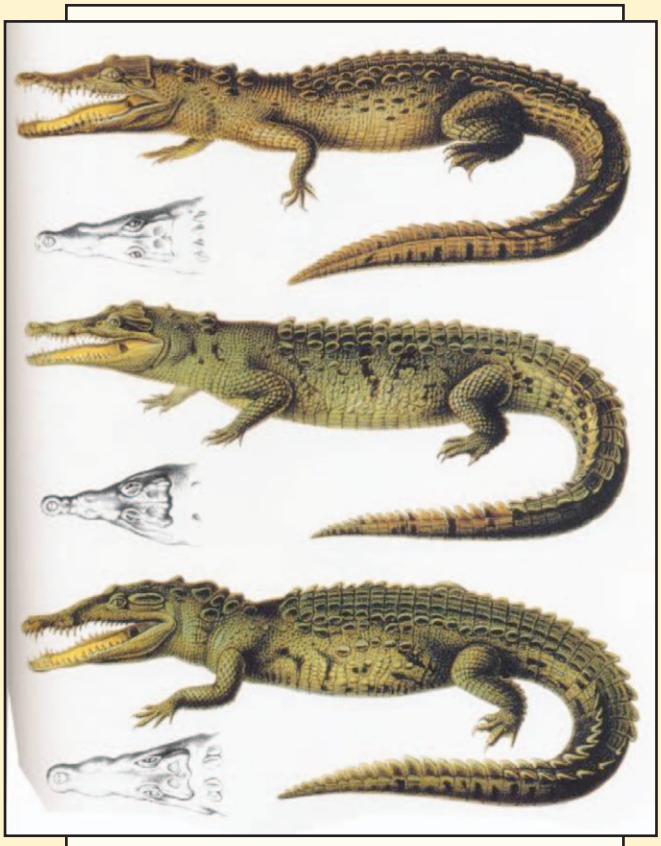


Illustration of American Crocodile (*Crocodylus acutus*) [top] and Cuban Crocodile (*C. rhombifer*) from *Historia fisica, politica y natural de la isla de Cuba*, by Ramón de la Sagra in 1839–1856. Hybridization between these two species is a serious threat to the Cuban Crocodile. "It has been known that they have killed human beings. I shall recite an episode told me by Don Helvecio Lanier. Once while this gentleman was on the Isla de Piños at Nueva Gerona, one of the numerous prisoners of war interned there insisted upon bathing in a river which was known to be inhabited by a large Caiman. No sooner had he jumped in than he was seized by the beast and pulled under; his companions being infuriated laid traps and caught the animal, which they would have torn to pieces had not Sr. Lanier intervened asking them to allow him to remove the hide, after which they tore the body into bits. Nine foot Cocodrilos or Caimans are not to be feared, I myself have gone into lagoons up to my chest where they abound, and instead of attacking they have always run away."—Thomas Barbour and Charles T. Ramsden (1919), *The Herpetology of Cuba*

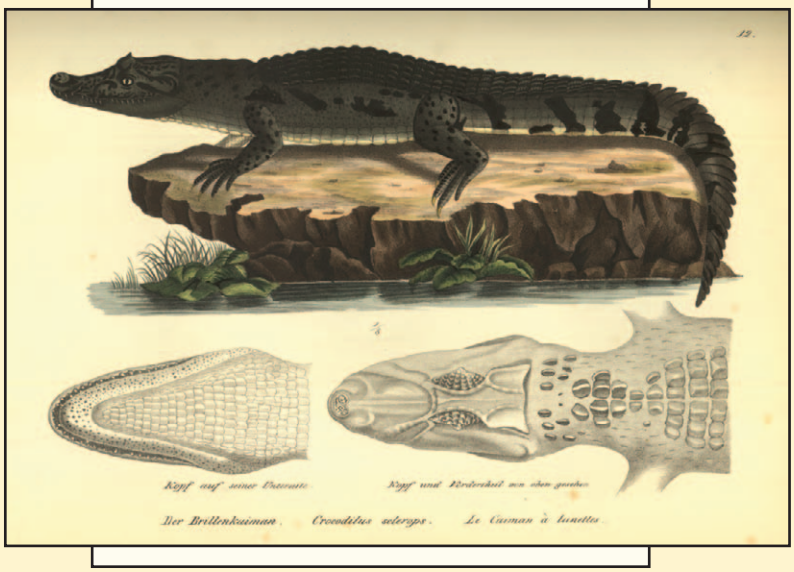
COLLECTIONS (ARCHIVES) OF THE ERNST MAYR LIBRARY OF THE MUSEUM COMPARATIVE ZOOLOGY, HARVARD UNIVERSITY



American Crocodile from *The Crocodilians, Lizards, and Snakes of North America*, by Edward Drinker Cope (1900). "Although seldom perturbed to any great degree by his own internecine activities, man is much aroused on those rare occasions when he himself falls prey to some lower animal. The importance of such occasions could easily be overemphasized. In discussing alligator attacks on man, I should like to note at the outset that this reptile is far less dangerous to man than is, say, the domestic dog. Rabid dogs, and even nonrabid ones, attack people far more often than do alligators; and the same can be said of domestic cattle and hogs. Alligator predation on man would not in fact merit lengthy discussion were not the literature so confused and contradictory in its treatment of the subject."—Wilfred T. Neill (1971), *The Last of the Ruling Reptiles; Alligators, Crocodiles, and their Kin*

This drawing of American Crocodile (*Crocodylus acutus*) is from *Études sur les reptiles*, by Auguste Henri André Duméril, Marie-Firmin Bocourt, and François Mocquard in 1870. "By far the most interesting thing about the feeding habits of crocodilians is the way they overcome large prey and reduce it to pieces that can be swallowed easily. This method is also used by crocodilians struggling over the same object. Once the jaws get a firm hold on the animal, the body of the crocodilian turns over and over, revolving rapidly on its long axis, so that one of two things happens: either the victim is turned over and over until it is rendered completely helpless, or it is simply twisted into two pieces. I have seen the photograph of a man who was given this treatment and had his arm torn from the socket. Oddly enough, he lived and was able to be photographed the day after the accident. The twisting action kept him from bleeding to death by closing the ends of the blood vessels instead of allowing them to remain open, as would have been the case if the arm had been cut off by a sharp knife. After the prey has been overpowered and reduced to pieces small enough to be swallowed, it is literally gulped down. If a piece includes big bones, these may be crushed by the jaws. Mouthfuls beyond a certain length may be tossed about until they will start end-first down the throat. The head is held high and tilted backward during this preliminary process, and is lifted above the surface if the crocodilian is submerged. Although large objects are always wolfed out of water, very small ones may be swallowed when the head of the crocodilian is under it and the jaws are tightly shut."—Clifford H. Pope (1957), *Reptiles Round the World*

Illustration from Heinrich Rudolf Schinz (1861), *Naturgeschichte und Abbildungen der Reptilien*. "Humans and crocodilians have been interacting since the dawn of civilization. The arena for this early interaction was probably Africa and Asia. It can be presumed that crocodilians preyed upon humans for food, but as man became a hunter, he stalked the crocodilians and was much more successful…Wherever and whenever humans meet crocodilians, there is bound to be fear, revulsion, and on occasion injury or death for either the person or the animal. Strangely, there is rarely any "hatred"... Crocodilians, however, have recently been the losers in this inter-species battle. While surviving for tens of millions of years, it has just been within the last hundred years that the few species remaining on earth have been severely threatened with extinction. The discovery that their hides make prized leather has been the chief cause of this demise. Secondary causes include hunting of the animal for sport and for food (including eggs) and loss of habitat due to human encroachment."—Steve Grenard (1991), *Handbook of Alligators and Crocodiles*

Red-bellied Mudsnakes (*Farancia abacura*; Fig. 1A) and Rainbow Snakes (*Farancia erytrogramma*; Fig. 1B) are relatively large species with geographic distributions restricted to the southeastern United States. Both species are highly associated with aquatic habitats, to the extent that at least one, the Red-bellied Mudsnake, has been described as "fully aquatic" (Lutterschmidt et al. 2006). Adults of both species have highly specialized diets: Red-bellied Mudsnakes feed primarily on aquatic, elongate, eel-like salamanders (Sirens [*Siren* spp., *Pseudobranchus* spp.] and Amphiumas [*Amphiuma* spp.]), while adult Rainbow Snakes feed almost exclusively on a stream-dwelling, catadromous fish, the American Eel (*Anguilla rostrata*; Neill 1964).

Because *Farancia* are difficult to observe or study, we know little about their ecology and natural history; however, both species are known to undertake terrestrial movements. Our knowledge regarding terrestrial activity of these snakes is based largely on captures from drift fences surrounding Carolina bays (e.g., Semlitsch et al. 1988); although data derived from these captures have expanded our understanding of the species, the spatial extent of terrestrial movements has not been reported. This information, however, is of relevance to the conservation of wetland-associated organisms (Semlitsch and Bodie 2003).

Farancia may undertake terrestrial movements for several reasons. Both species are generally thought to hibernate below ground or under woody debris adjacent to their aquatic habitats (Ernst and Ernst 2003; Gibbons et al. 1977; Neill 1948; Young and Gibbons 2008). Richmond (1945) suggested Rainbow Snakes were the most abundant snake in the sandy fields of New Kent County, Virginia, based on his observations that specimens were frequently discovered by plowing fields. In this region, snakes were observed more often on land than in the neighboring wetlands.

Farancia may emigrate from wetlands during drought (Seigel et al. 1995; Willson et al. 2006) but sample sizes from past studies have generally been small. In the only published radio-telemetry study of the genus, Martin (1998) noted that Red-bellied Mudsnakes (N = 3) had small home ranges and were highly aquatic, making only small movements overland to neighboring wetlands during drying conditions. Red-bellied Mudsnakes may move overland in response to significant rainfall events, based on a mass movement of juveniles across a two-lane highway through a freshwater marsh in Florida (Hellman and Telford 1956).

Both species nest on land and their nests are generally thought to be located close to wetlands (e.g., Neill 1964; Hall and Meier 1993). However, Red-bellied Mudsnake nests have been found 15 m and 46 m from lakes in Alachua Co., Florida (Auth

1992; Riemer 1957) and 91 m from a lake in Aiken Co., South Carolina (Neil 1964). Neil (1964) also noted a Rainbow Snake approximately 64 m from a lake in Richmond Co., Georgia, but the impetus for this movement is not known.

Methods.—Herein, we review our previously unpublished data on Red-bellied Mudsnakes and Rainbow Snakes found in terrestrial habitats >25 m from the nearest body of water. For Rainbow Snake captures, we also report the distance to the nearest body of water known to be inhabited by American Eels (when available). Distances were estimated through use of Geographic Information Systems, topographical maps, or Google Earth. Because water levels may fluctuate, the distances we report should be considered approximations, but they correspond to our impressions in the field.

To determine whether our observations of *Farancia* away from water were unusual events, we reviewed location data compiled by the Carolina Herp Atlas (CHA), an online database maintained by Davidson College and generated by voluntary submissions of amphibian and reptile observations in North and South Carolina (Price and Dorcas 2011). We first removed data from Aiken or Barnwell Counties, South Carolina, because many of the observations from these counties were not generated from incidental observations, but rather resulted from controlled trapping efforts for semi-aquatic snakes on the Savannah River Site (e.g., Durso et al. 2011). We also removed any remaining observations generated from trapping elsewhere, as indicated in the "Remarks" section of the data input form. Finally, we removed observations collected prior to 2000 to ensure currently available wetland boundaries were relevant to snake observations. Then, we used ESRI ArcMap 9.3.1 to measure the distance between each *Farancia* location and the nearest wetland boundary, as delineated by the National Wetland Inventory (U.S. Fish and Wildlife Service 2011). A value of zero was recorded if the observation was within a wetland boundary.

Results.—We compiled 60 and 18 observations of Red-bellied Mudsnakes and Rainbow Snakes, respectively, from our unpublished field notes and trap capture data (Table 1). Individuals of both species were observed considerable distances from the nearest body of water (up to 1288 and approximately 2000 m for Red-bellied Mudsnakes and Rainbow Snakes, respectively). We included 17 Red-bellied Mudsnake and six Rainbow Snake observations from the CHA (Fig. 2). On average, Red-bellied Mudsnakes submitted to the CHA were observed 62 m from the nearest wetland boundary (SD = 72.07 m, range 0–264 m) and Rainbow Snakes were observed 44 m from the nearest wetland boundary (SD= 44.91 m, range 0–117 m).

Discussion.—We demonstrate that both Red-bellied Mudsnakes and Rainbow Snakes undertake considerable terrestrial movements and these movements may not be unusual events. This information supplements similar and recent information on terrestrial movements of other snakes considered highly aquatic (Steen et al. 2011), and further emphasizes the important role of the terrestrial landscape to species that spend the majority of their time in wetlands. We are unable to determine why the snakes we observed were traveling overland. However, many of the small individuals captured in the spring were likely immature (Gibbons et al. 1977; Lutterschmidt et al. 2006) and dispersing to wetlands after overwintering and emerging from their nests (Gibbons et al. 1977). For example, our spring observations of four hatchling-sized Rainbow Snakes (captured in a large area of xeric sandhill habitat adjacent to the Canoochee River on Fort Stewart, Georgia [Table 1]) suggest that the coarse sandy soils of xeric sand ridges adjacent to perennial blackwater streams may be important nesting habitat, when available.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND PHOTOS BY D. STEVENSON

FIG. 1. A) Western Mudsnake (*Farancia abacura reinwardtii*), Cache River bottomlands, Johnson Co., Illinois, USA. B) Rainbow Snake (*Farancia e. erytrogramma*), Canoochee River, Liberty Co., Georgia, USA.

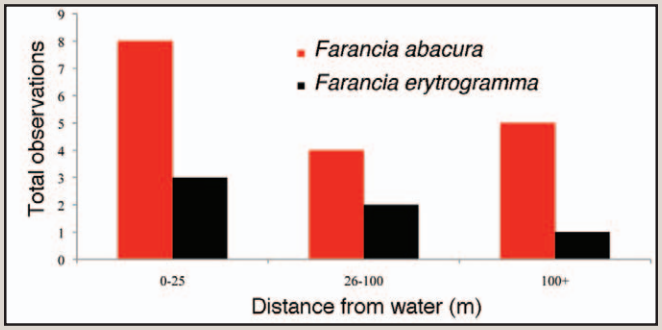

FIG 2. Distance to nearest body of water for Red-bellied Mudsnake (*Farancia abacura*) and Rainbow Snake, (*F. erytrogramma*) observations submitted to the Carolina Herp Atlas since 2000.

Sexually mature individuals were likely undertaking a nesting migration, dispersing to wetlands, or moving to a terrestrial overwintering site. Observations from Baker Co., Georgia (Table 1) suggest these animals may also travel overland in response to flooding events, as suggested by Hellman and Telford (1956). Only two captures from this site were recorded in seven years of trapping in a Longleaf Pine forest and both were in months of unusually high

TABLE 1. Information related to observations of Red-bellied Mudsnake (*Farancia abacura*) or Rainbow Snake (*F. erytrogramma*) located far (>25 m) from the nearest body of water. When the sex of a snake is known, it is indicated by M (male) or F (female). If no size data were available, but it is known whether the individual was an adult or juvenile, this is indicated by an A, or J, respectively. DOR = Dead on Road, AOR = Alive on Road.

flow rates for Ichawaynochaway Creek, the nearest body of water at this site (U.S.G.S. Water-Data Report GA-2005).

Results presented herein demonstrate that both Red-bellied Mudsnakes and Rainbow Snakes undertake long movements overland. We are unable to determine the cause or extent of these movements, or the frequency with which these snakes move onto or across the terrestrial landscape. Radio-telemetry studies of other aquatic snakes (e.g., *Nerodia* spp.) have demonstrated that they undertake regular terrestrial movements and terrestrial landscapes were identified as an important component of their life history (e.g., Camper 2009; Roe et al. 2003). The distances we report are well beyond the mean distances traveled overland by these other species (Camper 2009; Roe et al. 2003). Given the biology of *Farancia*, generating robust sample sizes for comparable radio-telemetry studies might be difficult; however, studies of this type are warranted, as they will likely generate novel natural history information related to aquatic home range size or the degree to which terrestrial habitats are used. An intact landscape to accommodate terrestrial movements is likely an important component to the life history of these wetland-associated snakes.

Acknowledgments.—We thank E. P. Cox and Auburn University librarians for providing reference materials. N. Watson provided assistance locating the Emanuel Co., Georgia individual. R. Wood, F. Granitz, B. Bond, and E. McGhee provided information related to the Pulaski Co., Georgia individual. We thank S. Price and M. Dorcas for maintaining the CHA and making the data available to us for this effort, as well as the volunteers who submitted their observations to that program. Authors have complied with all applicable institutional animal care guidelines and relevant state permits were obtained.

Northern Mexican Gartersnakes, *Thamnophis eques megalops*, feeding on *Spea multiplicata* in an Ephemeral Pond

The Northern Mexican Gartersnake, *Thamnophis eques megalops*, is the only subspecies of the Mexican Gartersnake occurring in the United States. Historically, it ranged from central Arizona and southwestern New Mexico southward through the Mexican states of Sonora, Chihauhua, Durango, Guanajuato, Hidalgo, and San Luis Potosí (Brennan and Holycross 2006; Rosen and Schwalbe 1988; Rosen et al. 2002), but is now thought to be at extremely low population densities or extirpated in New Mexico (Holycross et al. 2006). In Arizona, population declines have been recorded in approximately 83% (15/18) of the Mexican Gartersnake populations originally surveyed in the early to mid-1980s and re-surveyed in 1995–2000 (Rosen et al. 2002). Survey data from the Gila River watershed in Arizona and New Mexico during 2004–2005 suggest continued severe population declines and local extirpations (Holycross et al. 2006). These declines were considered significant enough that the Center for Biological Diversity petitioned (CBD) to list the Northern Mexican Gartersnake as Threatened or Endangered under the U.S. Endangered Species Act (CBD 2003). Although the petition was initially unsuccessful (USFWS 2006), the U.S. Fish and Wildlife Service (USFWS) later concluded that the Northern Mexican Gartersnake is threatened with extirpation, or may already be extirpated from 85–95% of its historical distribution in the United States and that listing was warranted (USFWS 2008). The USFWS expects to publish updated information in the Federal Register on the status of Northern Mexican Gartersnakes (J. M. Servoss, pers. comm.)

Northern Mexican Gartersnakes are associated with permanent water and cienega habitats containing aquatic vegetation and a wide range of terrestrial vegetation (Rosen and Schwalbe 1988; Rossman et al. 1996). Their prey consists primarily of fish, frogs and tadpoles, although invertebrates, lizards (T. R. Jones, pers. comm.), and mammals are also eaten (Garcia and Drummond 1988; Rosen and Schwalbe 1988; Van Devender and Lowe 1977).

Observations.—On 15 July 2012 at 2130 h following one of the first heavy monsoon rains in the area, a male Mexican Gartersnake was observed feeding on a Mexican Spadefoot (*Spea multiplicata*) in a seasonal pond at the Appleton-Whittell Research Ranch (AWRR) of the National Audubon Society, near Elgin, Arizona, USA. The pond, which had been dry since the summer of 2010 (R. Cogan, L. Kennedy, pers. comm.), filled earlier that day to approximately 150 × 30 × .5 m (L×W×D) from overflow of an adjacent dry wash which had also been dry since the previous summer (Fig. 1). A breeding aggregation (>50) of *S. multiplicata*, that had not been present on previous nights, was active in the tank. The 520 mm SVL snake was captured by hand, photographed, and released on site. The following morning during 0745–0950 h, five other Mexican Gartersnakes were observed basking at the bases of Sacaton grass (*Sporobolus wrightii*) surrounding the pond. Four were captured by hand, but the fifth eluded capture. The captured snakes included two males (505 mm, 520 mm SVL) and two females (675 mm, 737 mm SVL). The snakes were released at their site of capture following data collection. All five snakes captured were at or near sexual maturity. Male Mexican Gartersnakes from nearby Finley Tank, also at AWRR, are thought to reach sexual maturity when

FIG. 1. Ephemeral pond at the National Audubon Society Appleton-Whittell Research Ranch, Santa Cruz County, Arizona. Northern Mexican Gartersnakes, *Thamnophis eques megalops*, were observed basking at the bases of Sacaton grass, *Sporobolus wrightii*, in the left foreground and left rear shore of the pond.

FIG. 2. A Northern Mexican Gartersnake engorged on Mexican Spadefoots, *Spea multiplicata*, at the National Audubon Society Appleton-Whittell Research Ranch, Santa Cruz County, Arizona.

FIG. 3. Seven Mexican Spadefoots, *Spea multiplicata*, regurgitated by a female Northern Mexican Gartersnake, *Thamnophis eques megalops*, upon her capture at the National Audubon Society Appleton-Whittell Research Ranch, Santa Cruz County, Arizona. Toads were re-ingested by the snake prior to her release at the site of capture.

they are 410–580 mm SVL; females at SVL's between 550–700 mm (Rosen and Schwalbe 1988).

The four snakes captured on the morning of 16 July were engorged with anurans (Fig. 2). One female regurgitated seven *S. multiplicata* upon capture and palpation revealed two more. The seven regurgitated spadefoots, one female and six males, had a combined mass of 60 g (Fig. 3). The approximate mass of all nine spadefoots ingested by the snake was 77 g, representing approximately 39% of the total mass of the 200 g snake, recorded after she had re-ingested all seven of the regurgitated prey. No feeding or aquatic activity was observed during the morning of 16 July, indicating that the snakes had fed during the previous night or in the early morning hours prior to the initial sighting of two snakes basking at 0745 h.

Discussion.—To our knowledge, this is the first documentation of Mexican Gartersnakes feeding on any species of spadefoot and the first report of nocturnal foraging in this species. In contrast to reports stating that Mexican Gartersnakes are restricted to riparian habitats with permanent sources of water (Brennan and Holycross 2006; Rosen and Schwalbe 1988; Rossman et al. 1996), our observations raise the possibility that this species can occur, at least temporarily, in riparian areas where standing water is only seasonally available. In a study of Mexican Gartersnakes at Finley Tank in 2007, two neonates were found at the tank in July, the beginning of the monsoons, which had been dry since the previous winter, suggesting at least one adult female had successfully reproduced without access to a nearby permanent water source containing frogs or fish (d'Orgeix 2011).

The species is either extirpated or occurs at extremely low densities at the Babacomari River, which is the nearest large permanent water source 4.2 km N and downstream from the pond, and none has been seen since 2007 in a small rock pool in Post Canyon 1.5 km SW of the pond (d'Orgeix 2011). The nearest known population of Mexican Gartersnakes is 1.2 km distant at Finley Tank where individuals have been seen as recently as 2009 (d'Orgeix 2011). Although Finley Tank was once a permanent water source, it has contained water only intermittently since 2006 (d'Orgeix 2011). Following the July–August monsoons in 2011, Finley Tank went dry and did not fill again until the night we observed snakes in the pond. If the snakes we observed had emigrated from Finley Tank between the time of the pond filling and our observations, they would have had to have left Finley Tank as it was filling with rainwater and moved 1.2 km overland through open semi-desert grassland in 6–17 h. Even less plausibly, snakes could have followed the single connecting riparian corridor from Finley Tank to the pond (~2.3 km long) that would have required upstream travel against rapidly moving floodwaters carrying substantial debris. Last, none of the five snakes we captured at the pond were marked individuals from the Finley Tank population where all individuals encountered (N = 29) had been given unique identification marks and PIT tags from 2007 to 2009 although recapture rates were low (d'Orgeix 2011). These considerations collectively suggest that the snakes we observed were already present in the near vicinity of the pond before it filled.

Our observations raise the possibility that, under drought conditions, spadefoots are an important food source for Mexican Gartersnakes, and are taken during the brief time these anurans are breeding in ephemeral ponds. Snakes may then be aestivating when the pond is dry. Aestivation in snakes has rarely been documented, but the small aquatic snake *Seminatrix pygaea* aestivates in seasonally dry wetland and has been predicted to

survive multiyear droughts in this manner (Winne et al. 2006). However, we cannot exclude the possibility that the snakes are also feeding on other terrestrial organisms (e.g., lizards, rodents) when ephemeral sites are dry, or emigrating to other sites with permanent water.

To confirm whether our findings are more widely applicable to the ecology of Mexican Gartersnakes, additional surveys for snakes are needed at ephemeral sites in riparian habitat when spadefoots are breeding. Subsequent results may determine whether use of this previously unrecognized habitat and food source is more prevalent than previously thought and contribute meaningfully to recovery strategies.

Acknowledgments.—We thank Tom Jones, Joe Mitchell, Jeff Servoss, and two anonymous reviewers for providing comments and suggestions that improved this manuscript. Linda Kennedy and Roger Cogan at the National Audubon Society Appleton-Whittell Research Ranch provided plant identification data and pond measurements in addition to providing logistic support. This research was partially funded through a grant from the National Science Foundation under HBCU-UP (HRD-1036286) to C. d'Orgeix. Reasearch was conducted under an Arizona Game and Fish Department Scientific Collecting permit #566344. All applicable institutional animal care guidelines were followed.

Behavior of *Plethodon metcalfi* Following Anesthetization with Tricaine Methanesulfonate (MS-222)

Tricaine methanesulfonate (also called Ethyl 3-aminobenzoate methanesulfonic acid or MS-222) is commonly used as an anesthetic in fish and amphibian research. Because MS-222 generally appears to be safe and effective for a range of amphibian species, it is commonly used in the process of surgery or marking of animals (e.g., Chelgren et al. 2006; Osbourn et al. 2011; Peterman et al. 2008). Amphibian responses to anesthesia may be species-specific (Fellers et al. 1994), and a number of studies have performed multi-species evaluations of induction and recovery times (Cecala et al. 2007; Lowe 2004; Peterman and Semlitsch 2006). Recovery times of individuals following anesthesia have previously been reported as the time until first response to a stimulus (Cecala et al. 2007; Peterman and Semlitsch 2006), recovery of a righting reflex (Crook and Whiteman 2006), or recovery of normal motor function with no indication of sluggishness or disorientation (Cecala et al. 2007; Crook and Whiteman 2006). In many cases, researchers will face a trade-off between the desire to minimize the time that animals are in captivity and the need to ensure that animals have adequate time to recover from anesthesia before release.

As a practical consideration for field research, allowing amphibians adequate time to recover from anesthesia may be critical for ensuring that our research activities do not cause predation or desiccation-related mortality. Behavioral studies are also conducted on the assumption that released individuals are behaving normally between subsequent observations. Furthermore, many mark-recapture models for estimating population parameters are based on the assumption that all individuals in

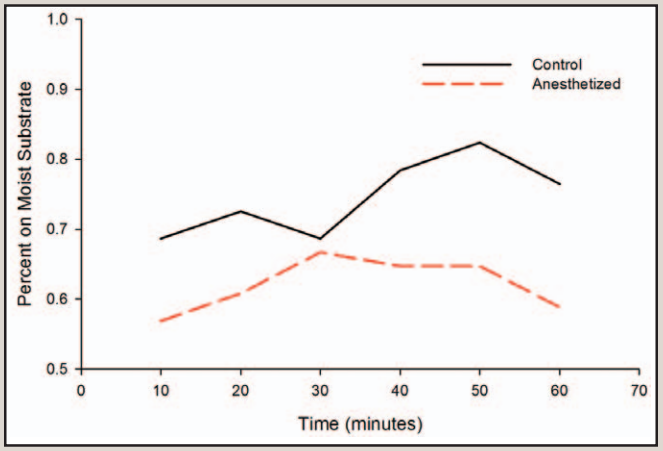

FIG. 1. Proportion of salamanders found on the moist substrate (N = 102).

a population (marked and unmarked) have an equal probability of survival and subsequent capture (Bailey et al. 2004). This assumption would be violated if the marking process resulted in elevated mortality or affected individual behavior in a way that altered the probability of future recapture. As a result, it is critical that we understand the extent to which the behavior of amphibians is impacted by the process of anesthetization and handling.

Many amphibians have narrow temperature and moisture requirements (Spotila 1972) and microhabitat selection behavior can be highly important for the regulation of water loss and desiccation risk (Heatwole 1960). As a result, we designed a laboratory experiment in which both un-anesthetized and previously anesthetized salamanders were presented with a choice between moist and dry substrate. We compared the substrate choice and movement behavior of control individuals with the behavior of individuals which had recently recovered full motor function following anesthesia. Ultimately, we sought to determine whether previously anesthetized individuals continued to demonstrate behaviors indicative of compromised function following their apparent recovery.

MATERIALS AND METHODS

Salamanders for this study were captured on the grounds of the Highlands Biological Station, Macon Co., North Carolina, USA (35.0546°N, 83.1902°W). A total of 102 *Plethodon metcalfi* (Southern Gray-cheeked Salamander) were hand-captured during nocturnal surveys in July of 2011. Each captured salamander was housed in an environmental chamber set to 16°C with a 14 h light/10 h dark photoperiod which corresponded to the natural photoperiod at the time. Salamanders were kept for a maximum of one week following initial capture, during which time they were housed individually in sterile plastic containers and were only exposed to other animals collected from the same area (within 400 m) during our experiment. Following completion of experimental trials, all salamanders were released at their site of capture.

To examine the effects of anesthetization with MS-222 on salamander behavior, we conducted a laboratory experiment in which we presented salamanders with a choice between moist and dry substrate. In this experiment, six choice test chambers were constructed out of rectangular plastic storage containers (61 × 42.7 × 16.8 cm) following procedures outlined by Crawford (2007). A piece of corrugated plastic was attached with silicone across the width of the containers in order to divide the chambers into equal halves. Four large panels were cut out of the lids of the containers and sealed with window screening. Both sides of the chamber were filled with commercial topsoil (about 20 cm^3) to the level of the plastic divider. Next, a moist and a dry side were randomly assigned within each container and a small spray bottle was used to add six ounces of water to the surface of the moist side of the chamber.

To begin this experiment, our MS-222 solution was prepared at a concentration of 500 mg/L and was buffered with 0.4 g of sodium bicarbonate (Peterman and Semlitsch 2006). Each salamander was being housed individually in a uniquely numbered plastic container and was selected for a trial and treatment group using a random number table. Six salamanders were randomly selected for each of 17 trials which were conducted from 16–29 July 2011. Three of these six salamanders were randomly selected to be anesthetized and were simultaneously placed in the MS-222 solution. Salamanders were considered fully anesthetized when they no longer responded to a light limb pinching (typically 5–10 min), at which point they were placed in fresh water to recover. Salamanders were considered fully recovered when they regained consciousness and seemed to have recovered full motor function, which we defined as the point at which salamanders appeared able to walk or swim normally with no sign of sluggishness or disorientation (Cecala et al. 2007). Specifically, only salamanders which showed a rate of body or tail undulations comparable to the rate of an unanesthetized salamander and which showed a rapid righting response while swimming were determined to be fully recovered. After each of the three salamanders for a trial had fully recovered from anesthesia (<15 min), salamanders were randomly assigned to one of the choice test chambers, which were positioned in an environmental chamber. All trials were conducted during the night photoperiod of the chamber and at a temperature of 20°C, which falls within the preferred temperature range of several *Plethodon* species (Spotila 1972). Prior to beginning the experiment, each salamander was gently placed under a Styrofoam cup on the barrier of the dry and moist side of the chamber and allowed to acclimate for five minutes. To begin each trial, the cups were removed and the lids placed back on the containers. Using a black light, we quickly inspected each of the six chambers at 10-min intervals for a total of 60 min. On a few occasions, a dim flashlight was needed to locate a salamander (<5% of checks). At each inspection, we recorded whether a salamander was on the moist or dry side of the chamber. If the salamander was on the center divider, then the snout position was used to assign the individual to either the moist or dry side of the chamber. In the last nine trials (54 salamanders), we also used fluorescent powder tracking (e.g. Rittenhouse et al. 2006) to obtain the movement paths of salamanders within the choice test chambers. In these trials, all salamanders had the posterior half of their body covered with fluorescent powder immediately prior to introduction to the choice test chambers. At the end of each 60-min trial in which we conducted powder tracking, we determined the distance travelled by each salamander by tracing their movement path with a piece of string which we measured on a meter stick. Following completion of each trial, we collected 100 ml of soil from the surface of each side of the chamber which was dried in an oven for 48 h in order to calculate the percent soil moisture of both the dry and moist sides. A t-test of independence was used to ensure that a significant difference in soil moisture existed between our moist and dry substrates. We then discarded the rest of the soil

and thoroughly washed each container. Fresh soil was used in each subsequent trial. Salamander test subjects were not re-used and were released at their site of capture following completion of their trial.

Data Analysis.—We examined the effects of anesthetization with MS-222 on three different measures of salamander behavior in this substrate choice test including: distance travelled, overall substrate preference, and final substrate choice. We used an analysis of covariance (ANCOVA) to assess the effect of anesthetization on distance travelled, independent of body size (snout-to-vent length). For this analysis, our measure of distance travelled represented the total powder trail length of the 54 salamanders for which this was measured. Additionally, we used a Fisher's Exact Test to determine whether salamanders which did not move during the course of our experimental trials were non-randomly distributed among our two treatments. To assess overall substrate preference, we classified salamanders according to whether they were observed on the moist side of the chamber greater than 50% of the time (at least four of six observations). Salamanders spending more time on the dry side or an equal amount of time on each side were classified as showing no preference for the moist side. We performed a G-test to assess the null hypothesis that salamanders spending a majority of their time on the moist side would be independently distributed between the anesthetized and control treatments. Finally, we considered final substrate choice to be the position of the salamander (moist or dry side of the chamber) on the final observation made during the experiment (at 60 minutes). We then employed a G-test to determine whether the final substrate choice of each salamander appeared to be independent of treatment. All statistical analyses were performed in the program R (R Development Core Team 2010).

Results

Powder tracking revealed that 51.9% of recently anesthetized salamanders did not move at all during the course of the experiment, while all control animals moved a minimum of 37 cm. Salamanders that failed to move at all during our experimental trial were clearly non-randomly distributed between treatments (Fisher's Exact Test: P<0.01). Overall, control animals moved significantly greater distances than recently anesthetized individuals (ANCOVA: $F_{1,51} = 56.62$, $P < 0.01$), and travelled an average of 125.6 ± 54.9 cm (mean ± 1 SD), while recently anesthetized animals travelled just 30.3 ± 40.4 cm (mean ± 1 SD). The mean masses of the control and treatment individuals were 2.70 ± 1.33 g (mean ± 1 SD) and 2.68 ± 1.23 g (mean ± 1 SD), respectively, and there was not a strong influence of body size on the distance travelled by each salamander (ANCOVA: $F_{1,51} = 0.86$, $P = 0.36$).

In our study, average soil moisture differed significantly between the moist and dry side of the choice test chamber ($t = 28.46$, $df = 101$, $P < 0.01$) and salamanders from both the anesthetized and control group spent the majority of their time on the moist side of the chamber (Fig. 1). Although salamanders in the control group were more often located on the moist side of the chamber than recently anesthetized salamanders (74.5% vs. 62.1% of observations), when salamanders were classified according to whether they showed a preference for the moist side of the chamber (4+ observations on the moist substrate), there was not a significant association between treatment and substrate choice (G-test: P = 0.126). Although not statistically significant, we found a trend indicating a stronger association between treatment and the final substrate choice of a salamander. At the end of the choice test experiment, 76.5% of control animals were located on the moist side of the chamber compared to 58.8% of recently anesthetized animals (G-test: P = 0.058).

Discussion

In this study, recently anesthetized salamanders were presented with a choice between moist and dry substrate. We found that salamanders that appeared to exhibit no sluggishness or disorientation after anesthesia were still likely to differ from control animals in aspects of their behavior. Overall, a large proportion of previously anesthetized salamanders did not move from their release location during our 60-minute experiment. Indeed, 51.9% of recently anesthetized animals did not move at all, while control individuals moved a minimum of 37 cm. The mean distance traveled by control salamanders was over four times greater than that of treatment individuals.

Salamanders in our two treatment groups differed greatly in movement distances, yet we did not observe a significant difference in the number of individuals selecting moist over dry substrates. Although a greater proportion of control individuals were observed on the moist substrate throughout our study, salamanders often switched between substrate types. In addition, our ability to make statistical inference based on substrate choice may be confounded by the large number of treatment individuals being classified as preferring the moist substrate based on their initial snout position even though they did not move at all during the study. An alternative definition for substrate choice, requiring that the salamander's entire body cross the center line may have been more appropriate.

In several previous studies, MS-222 appeared to have minimal effect on the health and survival of many amphibian species (Cecala et al. 2007; Peterman and Semlitsch 2006). A variety of measures have been used to assess amphibian recovery times after anesthesia, with one of the most conservative being the time to full recovery of motor function with animals showing no indication of sluggishness or disorientation (Cecala et al. 2007; Crook and Whiteman 2006). In this study, we investigated the behavior of salamanders that had recovered full motor function after anesthesia and found that these animals still appeared to behave differently from control individuals. Although we cannot distinguish the effects of anesthesia itself from the potential effects of stress or exhaustion due to partial submersion in the anesthetic solution, it is apparent that animals showing no visible signs of compromised function may still be incapable of behaving normally upon release in the field.

Researchers may be required to anesthetize amphibians for a number of purposes, such as surgery, marking, or photography (e.g., Chelgren et al. 2006; Kaiser and Green 2001; Osbourn et al. 2011; Peterman et al. 2008). This may lead to a trade-off between minimizing the time that animals are in captivity and ensuring that animals have adequate time to recover from anesthesia prior to release. Our study clearly indicates that researchers anesthetizing amphibians should account for the fact that some animals may not be capable of normal behavior even after they appear to be physically recovered from anesthesia. Due to the reduced level of movement and reduced ability of recently anesthetized salamanders to respond to substrate moisture, this study suggests that animals may face a temporarily heightened risk of predation and water loss if released too shortly after anesthesia. An important goal of future studies should be to more

precisely determine the amount of time required for released amphibians to be capable of resuming normal behavioral function following anesthesia. Due to the species-specific nature of physical recovery times (e.g., Cecala et al. 2007; Peterman and Semlitsch 2006), researchers should seek to identify the timeframe for behavioral recovery in their own study species. Additional research should also investigate the relative influence of handling stress versus anesthetization on behavior (e.g., Kinkead et al. 2006). This could potentially demonstrate an advantage of using anesthetics that require less handling time and/or do not require immersion in an anesthetic solution (e.g., cutaneous application of Orajel; Chen and Combs 1999).

Acknowledgments.—We thank M. Osbourn for providing constructive comments on this manuscript as well as M. Mackey and J. Voorhies for assistance in conducting the laboratory experiment. We also thank J. Costa and the staff of the Highlands Biological Station for the use of station property and facilities. This research was funded by a Thelma Howell Memorial Scholarship to GMC from the Highlands Biological Foundation; GMC was also supported by a Life Sciences Fellowship from the University of Missouri. Research was conducted under a North Carolina Wildlife Resources Commission collection permit (10-SC00405) and approved IACUC protocols through the University of Missouri (6144) and the Highlands Biological Station.

Within-Pond Selection of Water Depth for Oviposition in *Ambystoma maculatum*

Animals tend to select habitats in an optimal fashion, thereby maximizing evolutionary fitness (Huey 1991; Morris et al. 2008). For pond-breeding salamanders selection of oviposition sites within breeding ponds can have important consequences for successful hatching and larval success (Petranka 1998). Many aspects of reproduction in Spotted Salamanders (*Ambystoma maculatum*) have been investigated (see review in Petranka 1998) but few details regarding oviposition microhabitat selection are published. Females usually attach eggs to submerged twigs, tree branches, or aquatic plant stems (Egan and Paton 2004; Petranka 1998) and occasionally deposit eggs on pond bottoms (Sexton et al. 1986). However, little is known regarding depth of egg mass attachment. Oviposition studies comparing the total water depth at which egg masses occur relative to random locations in ponds indicate that most egg masses are deposited in shallower areas of ponds where warmer water accelerates development (Dougherty et al. 2005; Egan and Paton 2004). However, little attention has focused on the actual distribution of egg masses with respect to depth from the water surface.

Depth is hypothesized to be important for successful embryonic development for several reasons. Sufficiently submerged egg masses would remain protected from desiccation when water levels fluctuate or decrease over time (Marco and Blaustein 1998). Pond-breeding salamanders in the temperate zone typically oviposit just after the spring thaw when water levels are highest. The outer gelatinous envelope of the egg mass is hydrophilic and affords protection from desiccation and predators (Petranka 1998; Ward and Sexton 1981). However, when egg masses are deposited or attached too deep development may be negatively affected because temperature, light penetration, and dissolved oxygen concentration decrease with increasing water depth (Wetzel 2001). We examined the depth of *Ambystoma maculatum* oviposition sites in a single breeding season within a small permanent forest pond to determine if there was any evidence of depth selection. Because the tradeoffs to hatching success vary with depth, we expected that the egg mass distribution would be modal and reflect an optimal depth for embryonic development.

Methods.—The study location was a small (288 m^2) permanent pond in an upland portion of an eastern deciduous forested reserve near the Ausable River in Bosanquet Township, of southwestern Ontario (43.11958°N, 81.79574°W). The pond was constructed in 1973 to provide water for fire protection for an adjacent pine plantation. Forest canopy covered about 11% of the pond surface and the perimeter (54 m) vegetation was comprised of tree (30%), shrub (21%), and grass/forbs (49%). The pond averaged a 31-degree slope towards the deepest part of the basin (3.3 m). Emergent vegetation covered 5% of the pond. The sloping edges of the pond contained an ample accumulation of dead deciduous and coniferous twigs and branches that were used by spotted salamanders for egg attachment in each of the past 21 breeding seasons (pers. obs.). The pond lacked fish, but was inhabited by other potential predators including Green Frogs (*Lithobates clamitans*), Wood Frogs (*L. sylvaticus*), Eastern Newts (*Notopthalmus viridescens*), Snapping Turtles (*Chelydra serpentina*), Leeches (*Macrobdella* spp.), and Caddisflies (Order: Tricoptera) (pers. obs.).

We measured water depth from the surface to the top of each egg mass (to nearest 0.5 cm) using a wooden measuring stick within approximately one month after oviposition. Only modest rainfall occurred since the thaw (Environment Canada 2011) and it likely countered evaporation as the pond water level appeared relatively unchanged (pers. obs.). It is unlikely that we missed any egg masses due to the high water clarity when measurements were taken. All egg masses also appeared intact, suggesting that no major hatching or predation had occurred since oviposition. We assigned egg masses to one of twenty, 5-cm depth classes ranging from 0 to 100 cm. All egg masses in the pond were < 100 cm deep. We examined the pattern of oviposition using a *G*-test with William's correction applied (Sokal and Rohlf 1995). To determine if depth selection occurred we compared the observed frequency of egg masses to an expected frequency based on available surface area in each depth class. The expected frequency was determined by multiplying the total number of egg masses observed by the proportion of total area in each depth class (to 100 cm deep). To calculate the proportionate areas for each depth class we first determined the surface area of the pond as length × width × a shape factor of 0.92 (to account for the pond's rounded corners). We then divided the maximum depth of the first depth class by the tangent of the mean slope angle (31 degrees) to determine class horizontal width. We next calculated the pond area beyond that depth class by subtracting twice the class width from the original pond dimensions and multiplying the remaining length × width × 0.92. Subtracting this remaining area from the area that included the depth zone of interest gave the area of that zone; we repeated

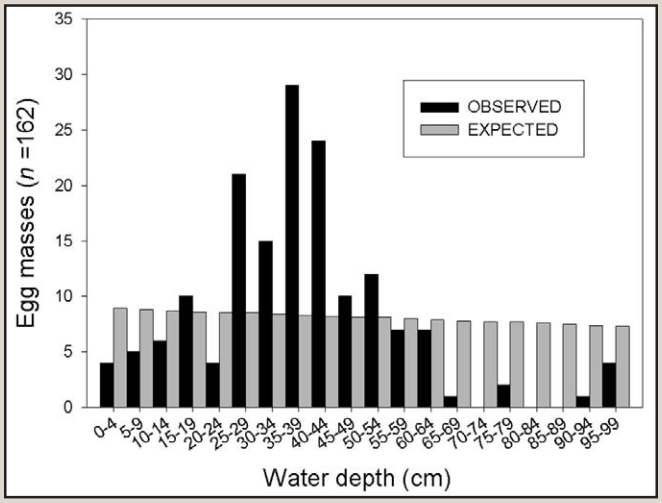

FIG. 1. Frequency distribution of *Ambystoma maculatum* egg masses with water depth from the surface shortly after oviposition in a 3.3-m deep pond in southwestern Ontario, Canada.

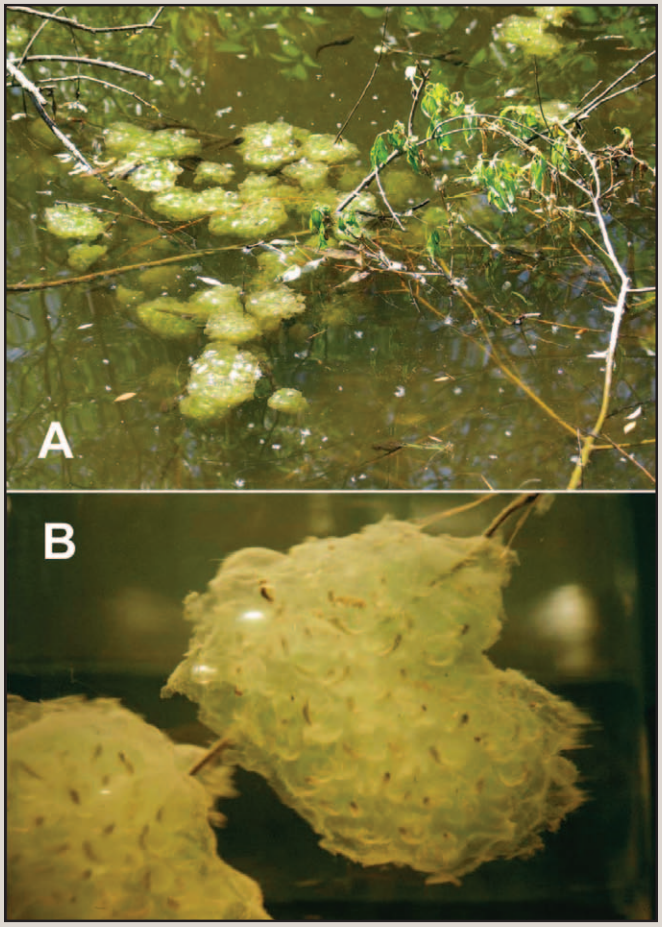

FIG. 2. Cluster of *Ambystoma maculatum* egg masses in the study pond (A). Most masses were attached to stems and twigs (B). Green color imparted to egg jellies by symbiotic algae (*Oophila amblystomatis*).

this process for each successive depth class. Calculating class area in this way accounted for basin shape with decreasing available area of depth classes in sequential bands from shore towards the pond center. Available area (0–100 cm deep = 103.6 m^2 total) decreased from 5.7 (proportion = 0.055) to 4.7 m^2 (proportion = 0.045) from the shallowest to deepest class yielding expected egg masses from 8.9 to 7.3 per class. We consider our available area estimates to be accurate as we carefully mapped pond perimeter and shape using a range finder and compass and determined average slope from multiple random measures along the pond perimeter.

We determined basic statistics and examined shape of the distribution using Lillefor's test and central moment statistics (Systat 12). We subsequently visited the pond five times through the season to observe the egg masses and their condition. Although we measured depth from the water surface to egg masses in just one season, we observed general oviposition patterns during 3–7 visits each year for 21 breeding seasons as part of a longer amphibian monitoring program (unpublished data).

Results.—Mean oviposition depth was 37.9 ± 1.41 cm SEM (median 38.0 cm); range 3.0–95.0 cm, N = 162 (Fig. 1). Egg masses were not distributed as expected with depth class (G = 148.5, df = 19, P < 0.001). Greater use than expected occurred in the 25–29 to 50–54 cm depth classes (Fig. 1). The distribution pattern was bell shaped (Fig.1), but differed significantly from an expected normal curve (Lillefor's test D = 0.0996, P<0.001) with a right-skew ($g1$ = 0.7492) and leptokurtosis ($g2$ = 1.6029). All masses were attached to twigs and stems within 2.0 m from the pond edge and most egg mass envelopes were clear and impregnated with symbiotic algae (*Oophila amblystomatis*) (Fig. 2). The small amount of emergent vegetation (*Typha latifolia*) was not used for egg attachment sites.

Discussion.—Oviposition sites in the pond were non-random. Distribution of available debris for attachment was not measured but it was abundant, appeared relatively even dispersed, and it extended from the water's surface further and deeper into the pond beyond the furthest occurring egg masses. Attachment sites thus appeared not to be limited. Our observations indicated that all egg masses occurred in shallower sections of the pond (< 2.0 m from edge, < 1.0 m deep) similar to the findings of others who examined pond depth where *A. maculatum* egg masses occurred. Egan and Paton (2004) found that egg masses were deposited in shallower water (mean 51.2 cm, range 0–220 cm) compared to mean maximum pond depth (107 cm) in 79 ponds in Rhode Island. Similarly, Dougherty et al. (2005) found that egg masses occurred in water averaging 37 cm relative to depths at randomly selected locations averaging 46 cm in a single pond in Ohio.

We also found a strongly leptokurtic unimodal distribution pattern of egg mass depth suggesting that females preferentially oviposited at ca. 38 cm below the water surface (Fig. 1). We are aware of only two other studies that examined *A. maculatum* oviposition sites with respect to water depth from the surface. Brodman (1995) found that females laid egg masses non-randomly in large clusters on submerged logs and emergent vegetation ca. 10–25 cm deep in an Ohio pond with 1.0 m maximum depth. He concluded that the success of hatching at this depth was attributable to warmer temperatures and presence of symbiotic algae relative to deeper waters. In North Carolina, 26% of 513 *A. maculatum* egg masses were <10 cm from the water surface and the remainder were at greater depth (Petranka, unpubl. data, reported in Starnes et al. 2000).

Six possibly adaptive reasons for the oviposition depth pattern we observed are oxygen levels, spring freezing events, water level fluctuations, sufficient light for symbiotic algae, protection from the harmful effects of UV-B, and predation by invertebrate and vertebrate predators (other amphibians and reptiles). Attachment of egg masses in midwater likely functions to prevent eggs from slipping to pond bottoms where oxygen levels are low (Duellman and Trueb 1986). We found DO_2 was 8.4 ppm in both spring and summer at 10 cm depth but did not measure concentrations across the complete depth profile. Eggs that are deposited in shallow depths may also be subjected to occasional mortality from freezing (Ireland 1989; Wells 2007). Return of ice with cold weather after initial thawing occurs occasionally in this region. During one year we observed several dead adults apparently frozen while exiting the pond. Water level tends to drop by mid-summer in this pond each year by 0–75cm (average fluctuation 25.3 ± 4.7 cm, N = 21 y). Considering that *A. maculatum* eggs hatch within 20–60 d (Harding 1997, June–July in this pond, pers. obs.) the mean depth we observed of 38 cm would leave most egg masses submerged and protected from desiccation during the low water levels of most summers (79.6% of masses > 25.3 cm deep). Virtually all egg jellies we observed were transparent (a few were white) and impregnated with symbiotic unicellular algae (*Oophila amblystomatis*). The oviposition depths we observed also place egg masses at a level where temperature would be warm and optimal light levels occur for development, algal growth, and protection from UV-B. Ultraviolet light can harm salamanders but most UV-B attenuates within 10–20 cm from the surface in natural waterbodies (see references in Crump et al. 1999). However, *A. maculatum* embryos are not particularly sensitive to elevated levels of UV-B and are thought to be at low risk in natural situations (Crump et al. 1999; Starnes et al. 2000).

The thick, firm egg jellies of *A. maculatum* are considered to provide protection from predators (Ward and Sexton 1981) and desiccation (Petranka 1998). We observed adult Red-spotted Newts (*Notopthalmus v. viridescens*), large overwintered Green Frog tadpoles (*Lithobates clamitans melanota*), and leeches (*Macrobdella* spp.) preying upon egg masses, but losses appeared minimal. High densities of newts may be capable of eliminating virtually all *Ambystomata* eggs in small ponds (Wells 2007) and *L. sylvaticus* tadpoles are capable of inflicting high levels of mortality on *Ambystoma* eggs (Petranka 1998). Our observations suggested that *N. viridescens* and *L. syvaticus* densities were moderate and low, respectively, in this pond in most years (3–7 visits/y, N = 21 y). Large Caddisfly larvae can feed on *A. maculatum* eggs (Rowe et al. 1994; Stout et al. 1992) and occur in the pond, but have not been observed feeding on eggs (pers. obs.). Another potential predator is the Snapping Turtle (*Chelydra serpentina*) which has been noted to feed on frog eggs (Steyermark et al. 2008) and *A. maculatum* (life stages other than eggs) (Ernst and Lovich 2009). A large Snapping Turtle resides in the pond but we have not observed it feeding on salamander eggs. Although our detailed study of oviposition depth selection involved only one pond and one season, our results and observations monitoring this pond for 21 years suggest that female *A. maculatum* choose oviposition sites that would provide optimal conditions for embryonic development in most years. Our observations of the distribution of egg masses supports the anoxia, desiccation, freezing, symbiotic algal, and predation hypotheses. Further research examining the processes and mechanisms of factors affecting developmental success is warranted.

Acknowledgments.—We thank the Ausable–Bayfield Conservation Authority for permission to access the site. This work was conducted under an OMNR Wildlife Scientific Collector's Authorization and was approved by the Lakehead University Animal Care Committee. An NSERC Discovery grant provided funding. J. Rowley and two anonymous reviewers made helpful suggestions to improve the manuscript.

Estimates of Tag Loss for Loggerhead Sea Turtles (*Caretta caretta*) in the Western North Atlantic

Capture-mark-recapture (CMR) research can provide valuable information on the survival rates, movements, population sizes and trends, growth rates, demographics, and other life-history parameters of wildlife populations (Williams et al. 2002). However, in order for CMR research to be accurate in the estimation of these parameters, a reliable method needs to be used to mark animals. Nevertheless, tag or mark loss occurs since no marking system is infallible. This loss, if not accounted for, can bias estimation of population parameters and abundance (Arnason and Mills 1981; Cowen and Schwarz 2006; Frazer 1983; McDonald et al. 2003).

The inability to recognize a mark (hereafter referred to as tag loss) generally has been measured using simple models that evaluate tag retention by monitoring groups of double-tagged animals and quantifying those that were recovered with one and two tags (Seber 1982). However, the assumption that the two tags have an independent rate of loss was not found to be true for sea otters (Siniff and Ralls 1991), black bears (Diefenbach and Alt 1998), fur seals (Bradshaw et al. 2000), leatherback sea turtles (Rivalan et al. 2005), or elephant seals (McMahon and White 2009). Furthermore, Seber's (1982) model only calculates discrete rates of tag loss that might not be accurately extrapolated to the end of the

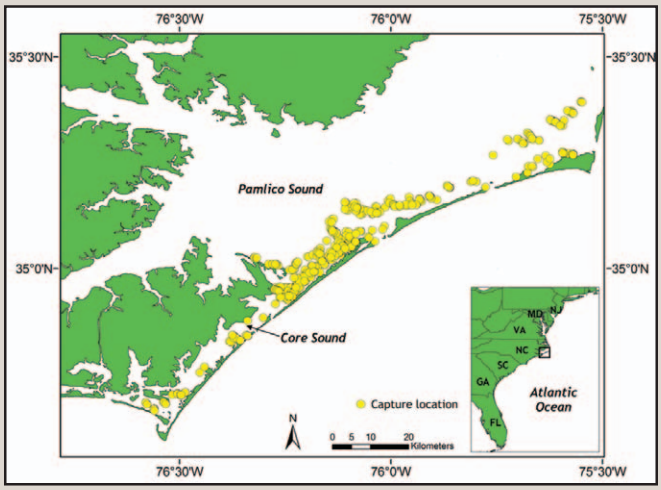

FIG. 1. Loggerhead Sea Turtles (*Caretta caretta*) were captured in fishing gear set in Core and Pamlico Sounds, North Carolina, United States. Inset shows position of main figure within the east coast of the USA.

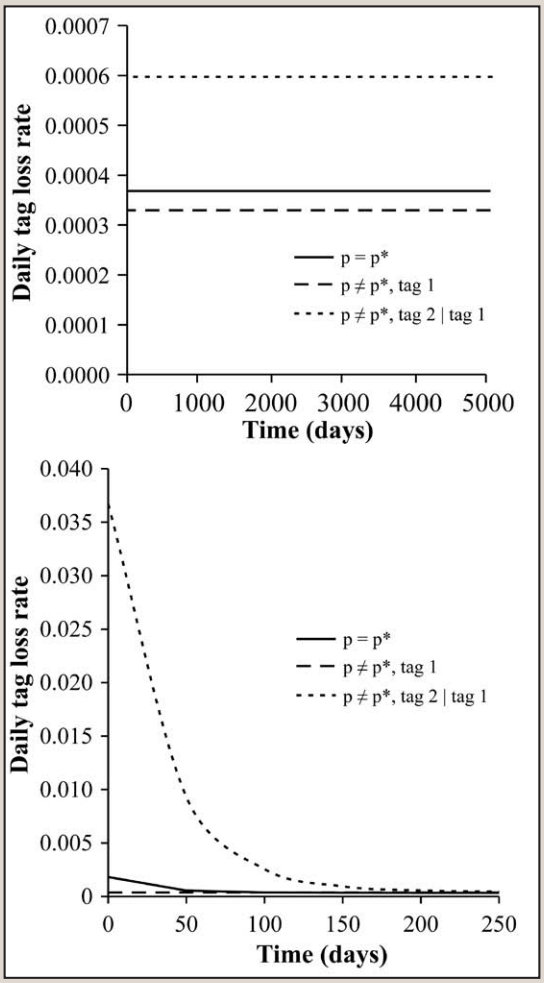

FIG. 2. Daily tag loss rate estimated for Data Set 1 (all individuals that received a PIT tag) using model A, the best fit model, which had a constant tag loss rate over time (upper panel). Daily tag loss rate estimated for Data Set 2 (only those individuals that received a PIT tag during initial capture; lower panel). The best fit model for DS2 was Model D with $p \neq p^*$, which resulted in model A for Inconel tag one and model D for Inconel tag two.

CMR study. Therefore, new methods were developed to address some of these limitations (Diefenbach and Alt 1998; Pistorius et al. 2000; Rivalan et al 2005; Schwartz et al. 2012). One of the models, described in Rivalan et al. (2005), takes an integrative approach that provides an estimate of tag loss rate while allowing for several tag shedding possibilities.

Loggerhead Sea Turtles (*Caretta caretta*) are long-lived, slow-growing animals that spend portions of each life stage in various oceanic and coastal environments (Meylan and Ehrenfeld 2000). In addition, they are vulnerable to many sources of mortality, most notably incidental capture in commercial fisheries (Lewison et al. 2004). Consequently, there is an urgent need to assess and protect their populations from extirpation (National Research Council 2010). Many turtles have been tagged in long-term, in-water studies so that aspects of their cryptic life history can be revealed (see Chaloupka and Musick 1996 for a review). Identification of individual sea turtles is generally accomplished through the use of metal or plastic flipper tags and Passive Integrated Transponder (PIT) tags (Balazs 1999). Efforts to develop photo identification techniques for turtle identification are also becoming more common (Lloyd et al. 2012; McDonald and Dutton 1996; Reisser et al. 2008; Schofield et al. 2008) Previous studies have attributed tag loss in sea turtles to a variety of reasons including turtle species, size of turtle, position of tag, tag material, poor application of the tag, or environment of the turtle (Alvarado 1993; Balazs 1982; Bjorndal et al. 1996; Henwood 1986; Limpus 1992; Parmenter 1993; Reisser et al. 2008; van Dam and Diez 1999).

The first objective of our study was to determine the tag loss rate of Loggerhead Sea Turtles in Pamlico and Core Sounds, North Carolina, USA. We have been double-tagging sea turtles with Inconel metal tags since 1989 and additionally tagging with PIT tags since 1995. We estimated tag loss using the maximum likelihood method in Rivalan et al. (2005), which makes two assumptions: 1) PIT tag loss is negligible and 2) the probability of a turtle not being observed again is the same for individuals tagged initially with or without a PIT tag. The second objective of our study was to determine the ramifications of the two assumptions and to explore if they were valid assumptions for our data set.

Materials and Methods.—We handled Loggerhead Sea Turtles incidentally captured in pound nets, long haul seines, and trawlers in Core and Pamlico Sounds, North Carolina, from June through December, 1989 to 2010 (Fig. 1). Core and Pamlico Sounds are a part of the Pamlico-Albemarle estuarine complex, the largest estuarine system (6630 km^2) in the southeastern United States. This system, which is bounded on the east side by the Outer Banks barrier islands, consists of lagoonal-type ecosystems that are shallow (the mean depth of Pamlico Sound is 4.5 m; Core Sound is 1.2 m), and productive (Copeland and Gray 1991; Roelofs and Bumpus 1953).

We recorded standard straight-line carapace length (SCL, notch to tip) to the nearest 0.1 cm. We applied Inconel metal alloy size 681 self-piercing tags (National Brand and Tag Company, Newport, Kentucky, USA) with approximately half the length of the tag to the trailing edge of both rear flippers, just anterior to the first large scale (Balazs 1999). We chose the rear instead of front flippers as we found some turtles were becoming entangled in the mesh of pound nets when the tag was on either front flipper (NMFS, unpubl. data). Beginning in 1995, we additionally injected unencrypted PIT tags (Destron-Fearing Corp., South St. Paul, Minnesota, USA, 125 kHz) subcutaneously approximately 1 cm anterior to the second most proximal scale of the trailing

margin of the left or right front flipper, or in the triceps superficialis muscle of the left front flipper; thus, all turtles were triple tagged beginning in 1995. We initially scanned all turtles to determine if they already had a PIT tag; if none was found, we scanned each PIT tag both before and after insertion to ensure it was functioning. After tagging, we released turtles in the vicinity of their capture locations. When a turtle was recaptured, we recorded all tags still detectable on the turtle. Only three of the recaptured turtles were recovered by researchers outside of our group who did not scan for a PIT tag, thus having a negligible effect on our results.

To determine daily tag loss rate, we used the integrative model of tag loss developed by Rivalan et al. (2005). We converted turtle capture histories so that the data provided time intervals (in days) for the following tag loss categories: N_{22} is the number of days that the recaptured turtle had retained both Inconel tags; N_{21} is the number of days during which the recaptured turtle had lost one of its Inconel tags; N_{20} the number of days during which the recaptured turtle had lost both Inconel tags (and only the PIT tag remained for identification); N_{11} is the number of days during which the recaptured turtle that had lost one of its Inconel tags was released with one tag and was recaptured still retaining that one Inconel; and N_{10} is the number of days during which the recaptured turtle that had lost one of its Inconel tags was released with one tag and was recaptured without any Inconel tags (and only the PIT tag remained for identification). For example, if a turtle was recaptured three times (first event with two tags, second event with one tag, and third event with one tag), then one would calculate the time intervals for N_{22}, N_{21}, and N_{11}.

The maximum likelihood method described by Rivalan et al. (2005) makes two assumptions: 1) that PIT tag loss is negligible and 2) that those individuals tagged initially without a PIT tag have the same probability of not being observed again as those individuals who initially received a PIT tag. We addressed the first assumption by calculating the percentage of recaptured turtles whose PIT tags were no longer detectable. We addressed the second assumption two different ways. First, we separated turtles into two different groups: turtles that were triple-tagged (2 Inconels and 1 PIT) and turtles that were double-tagged (2 Inconels). We compared the percent of triple-tagged turtles that were never recaptured to that of double-tagged turtles that were never recaptured to test the assumption that tag loss rate was the same for individuals in both groups. Confidence intervals for each of the proportions were calculated using Wilson's (1927) confidence interval and the confidence intervals were compared to see if they overlapped. Second, we created two data sets to see if the shape and magnitude of tag loss over time was the same when analyzing the data using the methods of Rivalan et al. (2005). The first data set (DS1) included all tagged individuals in the study who received a PIT tag at some point (N = 2811). The second data set (DS2) included only those individuals that received a PIT tag on their first capture event (N = 2606); thus, DS2 is a subset of DS1. By analyzing both data sets separately, we were able to determine if tag loss rate was affected by including those individuals that were not PIT-tagged during their initial capture event.

Each data set was then used to find daily tag loss rate, using maximum log-likelihood to find parameter values for:

$$p(t) = \frac{1-\min_t}{1+e^{(a_0(a_1-t))}} + \min_t \quad \text{where} \quad \min_t = \frac{a_4}{1+e^{(a_2(a_3-t))}}$$

where p is the probability of tag loss; t is time; and a_0, a_1, a_2, a_3, and a_4 were model parameters with standard errors being estimated with the delta method (Rivalan et al. 2005). We used the software application TAG LOSS, Version 3.2.3 (Girondot 2011).

We modeled six different tag loss patterns, which can be found in Fig. 1 of Rivalan et al. (2005):

Model A, a constant daily tag loss rate;

Model B, a linearly decreasing tag loss rate;

Model C, a high tag loss rate that decreased over time to asymptote near zero;

Model D, a high tag loss rate that decreased over time to an asymptote above zero;

Model E, a high tag loss rate that gradually decreased over time, although not as a smooth function; and

Model F, an initially decreasing tag loss rate, which began increasing after a certain period of time.

Each model was fit for each data set assuming 1) probability of tag loss was equal for both tags ($p = p^*$) and 2) probability of tag loss was different for both tags ($p \neq p^*$). Tag loss rates were estimated for Inconel tags, not PIT tags, and the probability of tag loss for the second tag was a conditional probability. We selected the best model based on the lowest Akaike's Information Criteria (AIC; Akaike 1974) values.

Results.—From 1990 to 2010, we tagged 2811 loggerheads and recaptured 585 identifiable turtles, ranging from 44.1 to 102.5 cm SCL (mean ± SE, 64.7 ± 0.3) at initial capture. Recapture intervals ranged from 1 to 4725 days (mean ± SE, 507.1 ± 29.5). We triple-tagged (2 Inconel and 1 PIT tag) 2606 loggerhead turtles, of which 2021 or 78% (95% CI: 0.76–0.79) never were recaptured. We double-tagged (2 Inconel tags) 205 loggerheads which were PIT-tagged during subsequent recaptures, and of those turtles, 172 or 84% (95% CI: 0.78–0.88) were never recaptured. Based on our data, we were not able to detect the PIT tag for 44 of the 557 recaptures that were scanned for a PIT tag, resulting in a 0.079 failed detection rate over the duration of the 15 years that we were tagging with PIT tags.

For DS1, daily tag loss rate for $p = p^*$ was estimated at 0.00037 using model A (Table 1; Fig. 2; AIC = 788.29). Daily tag loss rate for $p \neq p^*$ was estimated at 0.00033 for tag one and 0.00060 for tag two using model A (Table 1; Fig. 2; AIC = 391.15). Daily tag loss rate for $p = p^*$ using model C was a decreasing function through time starting at a high of 0.00050 on day one and decreasing as time continued (Table 1; Fig. 2b; AIC = 788.81). Daily tag loss rate for $p \neq p^*$ using model C was a decreasing function through time starting at a high of 0.00044 for tag one and 0.00143 for tag two on day one and decreasing as time continued (Table 1; Fig. 2; AIC = 777.15). When fitting models B, D, E, and F, the parameter estimates all reduced to model A as the best fit to the data.

For DS2, daily tag loss rate for $p = p^*$ was estimated at 0.00040 using model A (Table 1; Fig. 3; AIC = 770.67). Daily tag loss rate for $p \neq p^*$ was estimated at 0.00037 for tag one and 0.00058 for tag two using model A (Table 1; Fig. 3; AIC = 767.40). Daily tag loss rate for $p = p^*$ using model C was a decreasing function through time starting at a high of 0.00058 on day one and decreasing as time continued (Table 1; Fig. 3; AIC = 774.03). Daily tag loss rate for $p \neq p^*$ using model C was a decreasing function through time starting at a high of 0.00052 for tag one and 0.00122 for tag two on day one and decreasing as time continued (Table 1; Fig. 3; AIC = 767.90). Model D did not reduce to model A as in the other data set. Daily tag loss rate for $p = p^*$ started at a high of 0.0018 on day one and decreased to an asymptote of 0.00034 using model D (Table 1; Fig. 4; AIC = 757.57). Daily tag loss rate for $p \neq p^*$ reduced to a constant loss rate (model A) for tag one and remained a decreasing function with an asymptote for tag two (model D).

TABLE 1. Model parameter estimates (standard error) for the models that converged for each data set and the associated AIC values. Data sets are DS1, which includes all turtles marked during this study, and DS2, which includes only turtles that received a PIT tag during the initial capture event. If $p \neq p^*$, then the parameter estimates (standard errors) are listed as the parameter estimates for the first tag followed by the parameter estimates for the second tag. Parameters with dashes below them were not estimated for that specific formulation of the model.

Data set	Model	AIC	a_0	a_1	a_4
DS1	A; $p \neq p^*$	391.15	—	—	6.59×10^{-4} (5.7×10^{-5}) 1.19×10^{-3} (2.1×10^{-4})
DS1	C; $p \neq p^*$	777.15	-6.1×10^{-4} (6.57×10^{-6}) −12531.3 (138.12)	-1.1×10^{-3} (2.6×10^{-5}) −5943.0 (156.70)	—
DS1	A; $p = p^*$	788.29	—	—	7.36×10^{-4} (5.6×10^{-5})
DS1	C; $p = p^*$	788.81	-6.08×10^{-4} (5.76×10^{-6})	−12479.9 (122.68)	—
DS2	D; $p \neq p^*$	755.26	— -2.87×10^{-2} (2.9×10^{-3})	— −114.1 (16.46)	7.5×10^{-4} (6.3×10^{-5}) 8.7×10^{-4} (1.8×10^{-4})
DS2	D; $p = p^*$	757.57	-3.89×10^{-2} (1.5×10^{-3})	−167.7 (7.39)	6.8×10^{-4} (5.8×10^{-5})
DS2	A; $p \neq p^*$	767.40	— —	— —	7.4×10^{-4} (6.3×10^{-5}) 1.17×10^{-3} (1.9×10^{-4})
DS2	C; $p \neq p^*$	767.90	-7.3×10^{-4} (7.1×10^{-6}) -9.8×10^{-4} (2.2×10^{-5})	−10284.8 (113.5) −6845.6 (170.6)	—
DS2	A; $p = p^*$	770.67	—	—	8.08×10^{-4} (6.0×10^{-5})
DS2	C; $p = p^*$	774.03	-6.96×10^{-4} (6.5×10^{-6})	−10720.14 (104.82)	—

For tag one, the tag loss rate was a constant 0.00037, while for tag two, the tag loss rate started at a high of 0.0367 and declined to an asymptote of 0.00044. Model D with $p \neq p^*$ (which resulted in model A for tag one and model D for tag two) had an AIC value of 755.26. Finally, when fitting models B, E, and F, the parameter estimates all reduced to model A as the best fit to the data.

Discussion.—Careful consideration of assumptions should always be used when analyzing data. For Loggerhead Sea Turtles in North Carolina, Inconel tag loss rate estimates were different when including all individuals that were PIT-tagged in the study (DS1) than when restricting the analysis to only those that received a PIT tag during their initial capture event (DS2). Although daily tag loss rates were similar for both data sets, the first year for DS2 showed the greatest tag loss rate for the second tag, which could have an effect on tag retention rates over time. The estimation of tag loss using DS2 demonstrated that the probability of not being observed again was not the same for turtles that initially received a PIT tag as compared to those that were PIT-tagged later; therefore, the second assumption made in Rivalan et al. (2005) should be considered for other datasets that have not PIT-tagged individuals during the entire duration of their study. Additionally, a portion of turtles from DS1 could have shed their Inconel tags prior to being PIT-tagged, and thus their tag loss would not be noted, as they would not have been recognized as recaptures. We also found that the first assumption of the method was not met as PIT tag detection failure during the 15 years we used these tags was 7.9%, which was not negligible. How PIT tag loss affects the model outcomes is unknown at this point, but could be addressed by constructing a model with three different tags that can be lost at different rates. Based on these findings, we suggest that those marking turtles for mark-recapture use more than one type of tag. Furthermore, our decision to only include turtles that received a PIT tag during their initial capture event did lead to different tag loss rates over time. Thus, careful consideration of input data into the model should be used.

A constant tag loss rate, such as that found for Inconel tag one in DS2, could be an indication of well-applied tags, the effect of tag location, or the interval of recapture. We calculated a tag loss rate of 13% after one year for the first tag using model A with $p \neq p^*$ for individuals tagged in the rear flipper. In contrast, Gorham et al. (1997) calculated a tag loss rate of >50% after 440 days for loggerhead turtles tagged in the front flippers. Thus, tagging rear flippers might result in an increase in tag retention compared to tagging front flippers. However, a constant tag loss rate also could be a reflection of the long recapture intervals (2–4 years) that we recorded with some individuals. Because of a lack of data on recaptures during the time immediately following marking of these individuals, the model has little information to determine the shape of the tag loss rate function during the time interval immediately following marking. Thus, the model falls back to the simplest explanation, which is a constant tag loss rate over the entire time interval.

In our study, the daily loss rate for tag two given that tag one had been lost was a decreasing function that went to an asymptote of 0.00044. Rivalan et al. (2005) also found tag loss rate for Leatherback Sea Turtles, *Dermochelys coriacea*, in French Guiana, to be very high initially, followed by a rapidly decreasing probability of tag loss soon after application. However, they found this initial high tag loss rate for tag one while we found it to be true for tag two. They tagged the rear flippers with Monel tags and attributed tag loss over a short time scale to tagging failure caused either by human or mechanical error. Likewise, the loss of the second tag in our study could have been a result

of incorrect application of the tag or failure of the tag to lock properly. Over the course of our 21-year study, several different trained technicians applied tags, which may be responsible for some tagging failure.

Similar to Rivalan et al. (2005), we also found that the rate of losing the second tag was significantly higher given the loss of the first tag. Tissue necrosis could have increased tag loss dependency since individuals susceptible to tissue necrosis are likely to lose both tags (Rivalan et al. 2005). However, tissue necrosis may be more of a problem with leatherback turtles than with loggerhead turtles, as we did not encounter any loggerheads with tissue necrosis on our study site. Rather, a possible explanation for the tag loss dependency in North Carolina loggerhead turtles may be attributed to tagging failure as a result of human error, i.e., improper application of the tag. In other words, if the first tag was not applied correctly (either through improper technique or mechanical failure of either the tag or tag applicator), there was an increased chance that the second tag also would not be applied correctly, resulting in the second tag being lost as well.

Tag loss in sea turtles varies, depending upon turtle species, size of turtle, position of tag, tag material, environment of the turtle, and the experience of taggers (see Balazs 1982 for a summary). For example, van Dam and Diez (1999) reported an Inconel tag loss rate of 18% after 3 years for front-flipper-tagged Hawksbill Sea Turtles (*Eretmochelys imbricata*), much less than our calculated rate of 39% after 3 years, indicating that hawksbill turtles might have an overall higher tag retention rate for Inconel tags in their front flippers than loggerhead turtles tagged in their rear flippers. However, their large sub-adults and adults (>60 cm) were tagged with just external tags (no PIT tags), so the possible inability to identify recaptures due to the loss of external tags might have influenced their overall estimation of tag retention rates.

Although PIT tags have been described as being "permanent"(Gibbons and Andrews 2004), several sea turtle tagging studies, including this one, have reported a failure to detect these tags. Failure to detect PIT tags can be attributed to a variety of factors: tags can be expelled from the body or migrate internally, the PIT tag scanner or reader can fail to detect a tag that is present, or the tag itself can fail (Wyneken et al. 2010). Parmenter (1993) found an 8% failure rate of PIT tags in Flatback Turtles (*Natator depressus*) after two years, while van Dam and Diez (1999) saw up to 15% failure in their ability to detect PIT tags in hawksbill turtles after a five-year period. We failed to detect approximately 8% of the PIT tags in loggerheads over the course of the 15 years we used PIT tags. Despite this failure rate, there are many advantages to using PIT tags to mark sea turtles. Because the tags are internal, tag loss through abrasion is low to non-existent. In addition, they have very little negative impact on the turtle, including entanglement in fishing gear, provided the animal is of a sufficient size to receive the tag. Finally, although our failure rate to detect PIT tags was not negligible, it was substantially less than the tag loss rate of Inconel tags, which was about 13% each year.

To increase our tag retention rates, we followed the advice of previous researchers by applying more than one tag to each turtle, using two Inconel tags and a "permanent" PIT tag. Triple-tagging turtles in this way allowed for greater identification of recaptures and enabled us to take advantage of the benefits of using both methods of tagging. For example, metal, external tags such as Inconel tags do not require a special reader to view the tag. Additionally, the cost (US $70 for 100 tags) is substantially less than that of PIT tags (US $6–8 per tag). On the other hand, despite their higher costs and need for a reader, PIT tags are essentially permanent marks as they can potentially last for the lifetime of the animal. Therefore, we likewise recommend using PIT tags in conjunction with one or more external tags (such as Inconel) to maximize the probability of identifying a recaptured turtle.

Loggerhead Sea Turtles are a slow-growing, late-maturing species that conduct wide-ranging migrations, life-history traits that make them especially susceptible to overexploitation (National Research Council 2010). Successful management of these vulnerable populations requires an accurate accounting of their absolute abundance to properly evaluate potential impacts of management decisions (National Research Council 2010). Estimation of tag loss rates will help to correct for potential biases in models used to estimate population abundance and survival over time. This allows for increased accuracy of abundance and survival estimates used in population modeling and for management of sea turtle populations.

Acknowledgments.—We thank the many observers who have helped us to tag sea turtles throughout this long-term study and the fishermen for allowing us access to sea turtles captured in their fishing gear. The manuscript was improved by comments from M. Godfrey, A. Hohn, P. Marraro, K. Shertzer, and anonymous reviewers. Research was conducted under NMFS scientific research permit #1260 and #1551 and USFWS Permit #TE-676379. Products referenced are not endorsed by the authors or the agency they represent.

Neotropical squamates display a diversity of reproductive strategies, which plays a key role in the evolution of their life histories (Shine 2005). Communal nesting is a widespread reproductive behavior among reptiles (Doody et al. 2009; Graves and Duvall 1995). An important aspect of this behavior is the selection of nesting sites with optimal environmental conditions by females to guarantee reproductive success (Blouin-Demers et al. 2004; Brown and Shine 2005; Iraeta et al. 2007; Montgomery et al. 2011). Female nest-site choice is considered an important form of parental care in most squamates, which leave their eggs unprotected soon after oviposition (Blouin-Demers et al. 2004). Thus, elucidating the factors directing this behavior in any reptile species is fundamental to understanding its reproductive biology (Iraeta et al. 2007).

Reptile egg aggregation occurs when "animals deposit their eggs or young along with those of conspecifics" (Doody et al. 2009). Traditionally, this reproductive behavior has been related to limited availability of optimal incubation nest-sites and/or adaptive responses, such as increased fitness by egg aggregation (Braz et al. 2008; Montgomery et al. 2011; Radder and Shine 2007). However, testing these non-exclusive (constraints and adaptationist) hypotheses represents a major challenge for evolutionary biologists (Radder and Shine 2007). Among squamates, available information about communal nesting behavior is biased toward best-studied and conspicuous species (e.g., gekkonids, scincids, polychrotids, iguanids), whereas information about fossorial and semi-fossorial lizards (e.g., gymnophthalmids) is very scarce

because their eggs are difficult to find in the wild (Doody et al. 2009).

The family Gymnophthalmidae contains 213 species of relatively small to medium-sized lizards, with a great ecological and morphological diversity (Donnelly et al. 2006; Pellegrino et al. 2001). Nevertheless, little is known about reproductive characteristics of most species in this family, including social reproductive behaviors such as communal nesting. The genus *Cercosaura* contains 15 species, of which six are distributed in the Colombian Andes, Magdalena River Valley, and Amazonian lowlands (Hernández-Ruz 2005; Hernández-Ruz and Bernal-González 2011; Uetz et al. 2011). *Cercosaura ampuedai* inhabits the uplands at the eastern slope of the Cordillera Oriental of the Andes mountains, in the Departments of Boyacá, Cundinamarca, and Norte de Santander in Colombia, and in the state of Táchira in Venezuela (Hernández-Ruz 2005; La Marca and García-Pérez 1990; Sánchez et al. 1995). To date, the reproductive behavior and other natural history traits of this species remain poorly known (Hernández-Ruz 2005).

Herein, we describe four communal nests and a communal nestsite used by females of *C. ampuedai* and some ecological and reproductive features of this population. Additionally, we compare our observations with those reported for other lizards and discuss the possible causes of this behavior.

Materials and Methods.—A communal egg-laying site of *Cercosaura ampuedai* was found on July 2011 in a farm located at Vereda Santa Isabel, municipality of Toledo, Norte de Santander Department, Colombia (7.28341°N, 72.36866°W, 2580 m elev.), at the eastern flank of the Cordillera Oriental of the Colombian Andes. The farm has nearly 200 ha dedicated almost exclusively to livestock activities, but around 1 ha is planted with approximately 2000 rustic coffee trees shaded with *Musa* sp. trees. Historically, this zone has an extended rainy season (April to November), with a mean annual precipitation of 1255 mm.

We removed 26 eggs from the egg-laying site and put them into plastic dishes with soil from the collection site. We transported the eggs to the Laboratorio de Biología Reproductiva de Vertebrados at the Universidad Industrial de Santander (Bucaramanga, Colombia). We dissected ten randomly selected eggs, and raised the remaining (16) eggs in plastic dishes covered with 1 to 2 cm of moistened soil and incubated them at 18°C during ten days. At this time, we dissected ten other randomly selected eggs and incubated the surviving (6) eggs until hatching.

We measured egg mass with a precision (± 0.001 g) electronic balance (Precisa, Switzerland) the longest and shortest diameters with Vernier calipers (± 0.02 mm; Anyi Instruments Co., China), and estimated egg volume with the water displacement method (Magnusson et al. 2003). We fixed all embryos in 10% buffered formalin, preserved in 70% ethanol and staged according to the table of Dufaure and Hubert (1961) for *Zootoca* (*Lacerta*) *vivipara* (D-H stages). We deposited embryos and neonates in the Herpetological Collection of the Natural History Museum of the biology school at Universidad Industrial de Santander and coded as UIS-R (2551 to 73).

Results.—We found the eggs on a dry day in the rainy season by visual encounter surveys, during a field trip through the organic coffee shade plantation. The communal nesting site was a small area (~2 m^2) close to a decomposing tree trunk on the edge of the coffee plantation near a pasture, which is adjacent to a fragment of an Andean cloud forest (Fig. 1A, B). The egg-laying site was characterized by shaded humified soil, rich in decaying organic matter and vegetal detritus, such as leaf-litter from coffee, shade trees, and rotten wood.

Eggs were distributed in four communal nests (two inactive and two active), next to each other. The two inactive nests contained 32 and 37 eggshells that apparently successfully hatched based on the observation of a slit that occurs during the eclosion of neonates (Fig. 1C). The presence of newly empty shells suggests the nests were recently active. The two active nests contained 31 and 33 eggs at several stages of development from 33 to 44 D&H stage, and neonates (Fig. 1D). Six eggs hatched during the time of the discovery of the nests. In all cases, eggs were grouped in pairs between 10–20 cm deep, together with one adult, two juveniles, and four neonates (Fig. 1E). The arrangement of eggs in pairs indicates a fixed clutch size of two eggs per female; the embryos within each pair of eggs were always at the same development stage (Fig. 1F). The eggs had a mean length of 14.34 mm (± SD 1.42, N = 26), mean width of 9.67 mm (± SD 0.98, N = 26) and a mean volume of 723.45 mm^3 (± SD 147.48, N = 26). We also found a positive and significant relationship between egg volume and development stage ($R = 0.86$, $p < 0.001$, d.f. = 20). Neonates had a SVL of 22.5 mm (± SD 0.43, N = 8) and a mean weight of 0.26 g (± SD 0.02, N = 8). The only evidence of predation inside the communal nesting site was the presence of a coral snake, *Micrurus mipartitus*, a potential predator of adults and juveniles.

Discussion.—A communal nest may be the result of oviposition by several females in a selected site, the oviposition of multiple clutches by a single female, or a combination of both (Bock 1996; Montgomery et al. 2011). The presence of juveniles and neonates near the site of oviposition and the presence of several clutches with embryos in the same stage of development suggest that the communal egg laying of *C. ampuedai* reported here is the product of oviposition by multiple females in a selected site, without excluding the possibility that females may return several times to lay eggs. Additionally, the presence of eggshells, plus eggs and individuals in several development stages indicates this egg-laying site may have been used for an extended period of time.

We found eggs in pairs, at the same stage of embryonic development, indicating that clutch size in this species consists of two eggs. Hernández-Ruz (2005) found two clutches, each with two eggs, and recorded the presence of two oviductal eggs (one per oviduct) in this species. Thus, *C. ampuedai* apparently has an invariant clutch size, which is characteristic of the family and has been considered to be genetically determined (Fitch 1970; Sherbrooke 1975; Vitt 1982).

Communal egg laying has been reported in about 14 gymnophthalmid species belonging to different genera (see Doody et al. 2009 supplementary material; Doan and Castoe 2003; *Leposoma rugiceps*, Hernández-Jaimes, pers. comm.; *Cercosaura vertebralis*, Meza-Joya, pers. comm.). However, this number may underestimate the incidence of this behavior within the family, given that eggs are difficult to find because of the semi-fossorial lifestyle of most species. Hernández-Ruz (2005) suggested the presence of communal egg laying in a population of *C. ampuedai*, which is confirmed by our observations.

Several benefits, including an increased rate of hatchling survival, metabolic heating, and saturation of nesting sites to reduce predation, may be associated with communal nesting in lizards (Ewert and Nelson 2003; Graves and Duvall 1995; Montgomery et al. 2011). Communal nests may occur where suitable sites for egg deposition are scarce, and thus females are attracted to places where the hydric, thermal, and soil characteristics are more appropriate (Graves and Duvall 1995; Espinoza and Lobo 1996). Also, females may select sites used by conspecifics based on the presence of empty eggshells, even in the presence of potential predators (Brown and Shine 2005; Espinoza and Lobo 1996; Plummer 1981), similar to our observations.

Despite the benefits of communal oviposition, the repeated use of the same egg-laying site by one or more females during a long period of time may increase the probability that predators discover the eggs (Doody et al. 2009; Montgomery et al. 2011). Interestingly, we found a coral snake next to the nesting site, a potential predator of *C. ampuedai*. *Micrurus* snakes generally feed on fossorial species, including other snakes, caecilians, amphisbaenians, and gymnophthalmids (Maffei et al. 2009; Marques and Sazima 1997; Souza et al. 2011).

The communal oviposition behavior of *C. ampuedai* could result from environmental constraints, due to local scarcity of potential egg laying sites restricted to the coffee plantation. However, given that we found several communal nests in the same site, this could result in a benefit to the offspring from communal oviposition, which can be explained by the "adaptation" hypothesis. An alternative explanation is that the metabolic heat generated by embryos plays a key role in the development rate, producing larger and faster hatchlings (Ewert and Nelson 2003; Shine et al. 1995; Zbinden et al. 2006). However, Radder and Shine (2007) found that the presence of multiple eggs in contact does not have a significant effect on the increase of metabolic heat; in contrast, particular hydric conditions that occur inside communal nests could lead to a direct benefit in the fitness of the communal oviposition (Clutton-Brock 2009; Nowak 2006; Sachs et al. 2004).

Acknowledgments.—We thank Laboratorio de Biología Reproductiva de Vertebrados, Escuela de Biología (Universidad Industrial de Santander) for financial and logistic support and Ministerio de

Ambiente, Vivienda y Desarrollo Teritorial for collecting and research permits (2100-2-79969). We also thank C. Hernández Jaimes for reviewing the English. The manuscript was greatly improved by comments from J. M. Anaya Rojas and anonymous reviewers.

The Use of Visible Implant Alpha Tags for Anuran Tadpoles

Amphibians are one of the most threatened groups of vertebrates in the world and are currently facing major declines due to habitat loss, emerging infectious diseases, and climate change, leading many species to extinction (Stuart et al. 2004). To face this amphibian extinction crisis, there is an urgent need to gather data on the demography and ecological characteristics of amphibian species (Wake 2007). In most of these studies, it is necessary to be able to identify individuals across time to study density, growth trajectories, or habitat use. Date-specific cohort marks can be used for density estimates but when intending to quantify growth, movement or survival, marks have to allow identifying individuals. Such marks have to possess a set of characteristics. First, it should allow each individual to be identified accurately. Second, it should have a minimal impact on the individual and should not affect behavior, survivorship and catchability.

A variety of techniques are available for individual recognition in amphibians. For adult anurans, toe clipping was the method most commonly used since the 1950s (Martof 1953). It has been shown to be well-adapted and to have little impact for some amphibian species (Grafe et al. 2011), and studies focusing on physiological indicators of distress show no increased stress resulting from toe-clipping (Perry et al. 2011). One of the drawbacks of toe-clipping is that it may have an effect on recapture and survival for some species (McCarthy and Parris 2004). More recently, Passive Integrated Transponder (PIT tag) have been proposed for amphibians (Brown 1997) and proved to be particularly well-suited. Nonetheless, PIT tags are still limited in their use by their size and can only be inserted in adult amphibians of larger size (4 cm SVL). The use of color patterns via picture identification (Kenyon 2009) has also been proposed as an alternative technique for the identification of adult amphibians but requires a specific color pattern for each individual, as e.g. found in tropical amphibian species. Finally, Visual Implant Elastomers (VIE) may mainly be used for date-specific cohort marking. To allow individual recognition, VIE marks have to be placed in distinct body parts or to be coupled with toe clipping (Hoffmann et al. 2008). Several marking procedures have been employed in studies of larval amphibians including tail-clipping (Turner 1960), staining of the entire tadpole (Travis 1981), coded wire tags (Martin 2011) and picture identification (Ribeiro and Rebelo 2011). Nonetheless, few of these techniques are suitable for monitoring the entire lifespan of anurans from the tadpole to the adult stage.

One alternative technique to mark amphibians both at the adult and larval stage is VI Alpha tagging (© Northwest Marine Technology Incorporation). VI Alpha tags are small rectangles of an inert elastomer inscribed with an alphanumeric code. Tags are available in four colors providing 2600 unique alphanumeric codes. VI Alpha tags were initially developed for fishes (Karvonen et al. 2004), but they have been successfully used with others organisms such as shrimp (Arce et al. 2003) or seahorses (Woods 2005). In the last five years, VI Alpha tags have been tested successfully for use on caecilians (Gower et al. 2006; Measey et al. 2001), urodeles (Osbourn et al. 2011), and anurans (Chelgren et al. 2006; Heard et al. 2008; Pittman et al. 2008). None of these studies were able to assess whether VI Alpha tags can allow following an individual through metamorphosis.

In this study, we evaluated the use of VI Alpha tags to mark tadpoles of the anuran species *Alytes obstetricans* and tested whether the mark remains after metamorphosis. More specifically, we aimed to assess whether these tags can be used for ecological studies using individual recognition in *A. obstetricans* by determining: 1) the rate of tag loss, 2) the readability of the tag across tadpole development until metamorphosis, and 3) the effect of such tags on survival rate.

Materials and Methods

Study species.—Alytes obstetricans, the Common Midwife Toad, is a European species ranging from northern Portugal and Spain in the south to southern Belgium and Central Germany to the northeast. It is present throughout France, except in the high Alps. It ranges from the sea line up to altitudes of 2400 m in the Pyrenees. This species is known for its male parental care behavior. The male carries a string of eggs wound on its hind legs until they are ready to hatch. After three to six weeks, the male releases the hatching larvae into suitable water habitat. Tadpoles measure about 15mm just after hatching, but can reach up to 10 cm in total length before metamorphosis with a mean body size of 2.3 (Standard Deviation = 0.4 cm; Courtois et al., unpubl. data).

VI Alpha tags.—VI Alpha tags (© Northwest Marine Technology Incorporation) are 1.2 × 2.7 mm tags (Fig. 1) that are

subcutaneously inserted with a specific injector needle. Each tag is coded with black letters and numbers on a fluorescent colored background. In this study, we used tags with a yellow background. After tagging, the unique code remains visible to the naked eye under daylight and readability can be enhanced with UV light (delivered by © Northwest Marine Technology Incorporation; Fig. 1).

We collected 90 tadpoles at Gosner Stage 25 (Gosner 1960) from a large population in a trough in Balagué (Ariège, France, 42.963889°N, 1.025278°E) measuring 5.3 ± 0.7 cm in total length (including tail) and weighing 1.5 ± 0.5 g. We tagged 30 tadpoles on the ventral side and 30 dorsally, resulting in 60 tadpoles marked in total. In half of the cases (15 tadpoles in each group), we used a surgical glue to help healing and potentially prevent tag loss.

Tadpoles were first immobilized by immersion in ice-cold water (around 4°C) and were restrained by gently squeezing the body between the thumb and index finger. A 3-µm-wide needle was used to make a small first incision in the epidermis, and the tag was inserted under the skin using the supplied needle injector. Whilst this instrument is designed for direct injection of VI Alpha tags, prior creation of a skin incision expedited the injection process considerably (Heard et al. 2008). Tadpoles were handled with powder-free latex gloves during the tagging manipulation, but no gloves were used in subsequent manipulation. We did not experience any tadpole mortality related to the usage of Latex gloves as found in other studies (Cashins et al. 2008), either in the experiment described here or in field research done on the same species (Schmeller et al., unpubl. data).

VIE tags.—We marked 30 tadpoles with VIE (© Northwest Marine Technology Incorporation) tags (orange) in the back in order to compare mark loss and survival rate between these two tag types. VIE are biologically compatible polymers which are composed of a colorant and a curing agent. They are mixed in equal quantity just before use, resulting in a liquid. The liquid is then sucked into a syringe and injected dorsally under the skin of the tadpole, where it solidifies to a permanent mark. The mark remains visible with the naked eye, but visibility can be further increased using UV light.

Tadpole rearing.—The 90 tadpoles were kept together in an aquarium with constantly filtered and aerated water at 18°C, pH 6.9, and a photoperiod of 10 hours of daylight. The aquarium was cleaned and water was replaced once a week. The tadpoles were fed after water replacement with fish food tablets (Tetra TabiMin). They were kept for six weeks in order to monitor both tadpole survival, tag loss until metamorphosis, and readability after metamorphosis. Once a week we recorded whether the VI Alpha tag or the VIE tag was still present or not for each individual. We defined tag retention as the percentage of tags in each group that were still present at the end of the experiment (i.e., 42 days after marking). For the VI Alpha tag, when the tag was present, we noted its degree of readability (index 0: not readable, index 2: readable only with UV-light, and index 3: readable under daylight), and the Gosner stage of the tadpole (Gosner 1960). The Gosner stage varied from 25 (no limb bud) to 46 (complete metamorphosis). When the tag was lost, the tadpole was released back into the wild. When the tag was retained, the tadpole was released after completion of metamorphosis, usually after five to six weeks.

Statistical analysis.—Binomial generalized linear models (GLM) were run to explain tag retention at the end of the experiment as a function of place of injection (ventral or dorsal) and use of glue, using the software package R (http://cran.r-project.org/). The variable "presence" was binary, as either the tag was still present (1) or lost (0). Similarly, the same type of model was used to determine the effect of the factors "place of insertion" (dorsal or ventral) and "surgical glue" (use or not) on the readability of the VI Alpha tags. Readability was then defined as 0 when not readable (index 0) and 1 when readable either with day light (index 3 defined previously) or UV light (index 2 defined previously).

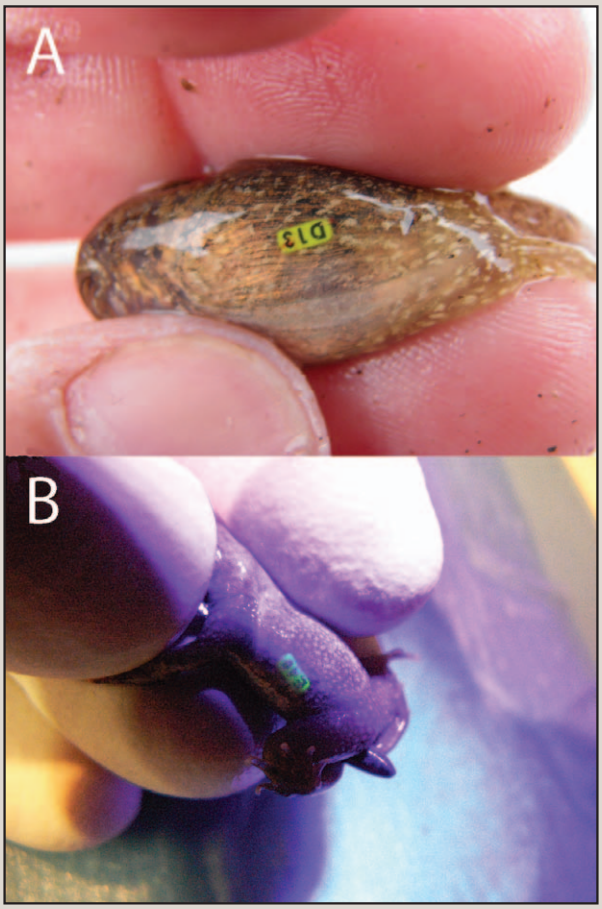

FIG. 1. VI Alpha tag inserted on the ventral side of *Alytes obstetricians* for a (A) tadpole and (B) recently metamorphosed frog when enhanced with UV-light.

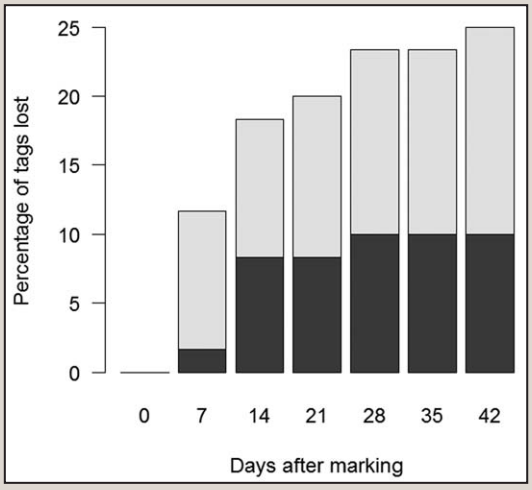

FIG. 2. Cumulative percentage of tags lost out of 60 as a function of the number of days after the injection when injected ventrally (in light grey) or dorsally (in dark grey).

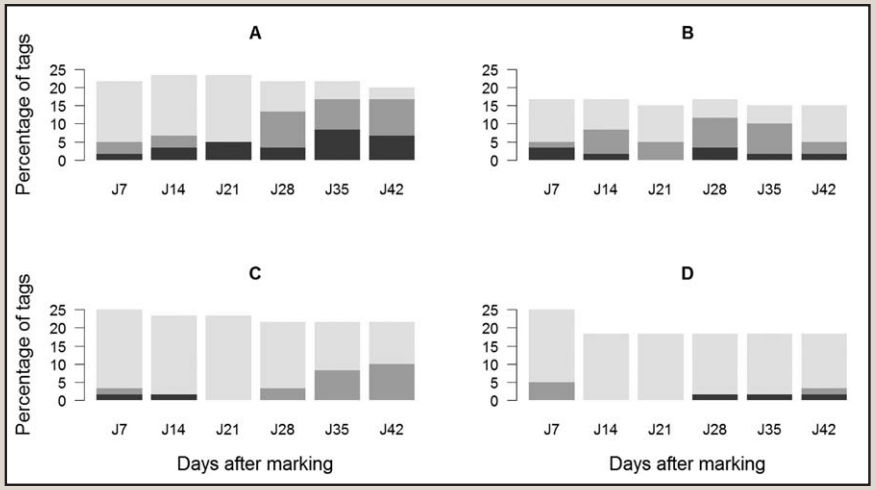

FIG. 3. Percentage of tags out of 60 that were not readable (black), readable only with UV light (dark grey) and readable under daylight (light grey) for (A) tadpoles marked dorsally without glue, (B) tadpoles marked dorsally with glue, (C) tadpoles marked ventrally without glue and (D) tadpoles marked ventrally with glue.

TABLE 1. Readability (% of readable tags—i.e., with readability index 2 or 3—at the end of the experiment) and tag retention (% of remaining tags at the end of the experiment) 42 days after marking.

	Readability (%)	Final tag retention (%)
Group A (dorsal, without glue)	67	80
Group B (dorsal, with glue)	89	60
Group C (ventral, without glue)	100	87
Group D (ventral, with glue)	91	73

RESULTS

In total, 15 tadpoles (25%) of the 60 individuals tagged with VI Alpha tags lost their tag before metamorphosis, of which 6 were marked ventrally and 9 dorsally. Tag retention tended therefore to be higher on the ventral than on the dorsal side (Table 1) but this difference was not significant (GLM, Deviance = 0.15, P = 0.38). Of the 15 tags that were lost, 10 were sealed with surgical glue and 5 were not, but the difference between groups was not significant (GLM, Deviance = 0.41, P = 0.14). Tag loss was most important in the dorsal group during the first 7 days (6 out of 9 tags lost), while tag loss in the ventral group was later with a maximum during the second week (5 out of 6 tags lost; Fig. 2). The retention rate of VIE-marked individuals was 100%.

Overall, 100% of VI Alpha tags were readable immediately after injection and an average of 87% were readable at the end of the experiment (Table 1). However, in 15 out of 45 cases UV light was needed to identify the VI Alpha tag code (readability index 2, Fig. 3). Our results show a higher readability on the ventral side than on the dorsal one (Table 2, GLM, Deviance = 0.43, P = 0.046). The better readability of the ventral tags compared to the dorsal tags was stable over tadpole development (Fig. 2). The use of surgical glue did not affect the readability of the tags (GLM, Deviance = 0.03, P = 0.58).

No tadpoles died during the experiment; the survival rate under controlled condition was therefore 100% for both the VIE tag group and the VI Alpha tag group.

DISCUSSION

Here, we tested the usage of VI Alpha tags for the marking of tadpoles of the species *A. obstetricans* under laboratory conditions. We found that tag retention was globally low (75%), rendering this technique unsuitable for Capture-mark-recapture studies on this species by introducing tag-loss bias. A previous study on the use of VI Alpha tags on amphibians demonstrated a level of 92.31% of tag retention for *Litoria raniformis* (Heard et al. 2008), which is comparable to the tag retention in the group in which we inserted VI Alpha tags ventrally and used no surgical glue to close the insertion (87%). Indeed, contrary to our expectations, the use of surgical glue did not increase the retention rate and seems to be more painful for tadpoles even under cold anesthetic (Calvez and Lelong, pers. obs.) and we therefore advise against its use. To counterbalance tag loss, Heard et al. (2008) proposed to couple the use of small VIE dot marks with VI Alpha tags in order to be able to identify an individual as marked even if the VI Alpha tag was lost, a suggestion also valid for *A. obstetricans* tadpoles as the VIE retention was 100% in our study.

The retention rate of the VI Alpha tags tended to be higher on the ventral than on the dorsal side, and additionally, the readability of the tags was significantly higher on the ventral side. Hence, ventral insertion of the VI Alpha tags should be preferred in future studies, especially as VI Alpha tags were readable after metamorphosis. Future studies should assess whether VI Alpha tags are readable in adult frogs that were marked as tadpoles. If so, VI Alpha tags may be useful in studies on breeding site fidelity, home range size, dispersal distances, infection load and habitat selection of amphibians (Pittman et al. 2008). Nonetheless, it should be noted that *A. obstetricans* tadpoles are especially large and tadpole marking in other species may not always be possible with this technique.

One advantage of VI Alpha tag compared to VIE is that only one injection is needed, as compared to multiple injections necessary for individual recognition using VIE-markers. Hence, the marking effort is strongly reduced per marking and recapturing sessions, allowing for an increased number of marked individuals and limiting the risk of mistaken identity. Readability of tags remains high (87%) even at the end of the experiment. Decrease of readability during the development of the tadpole and after the metamorphosis can be explained by the fact that tadpole skin becomes less transparent in tadpoles of high Gosner stage and even less in post-metamorphic tadpoles. VI Alpha tags are also a good alternative to more expensive marking techniques such as PIT tags. It opens up the possibility to work with smaller-sized amphibian species and larval stages as the minimum size for VI Alpha tags is 2 cm for SVL compared to 4 cm for PIT tags. Moreover, Alpha tags are flatter than PIT tags. Further, survival rate was 100% and we therefore agree with the assessment of Heard et al. (2008) that VI Alpha tags are a promising alternative to PIT tags for marking larval amphibians.

Future studies should be conducted to determine whether the results observed in this study are the same under field conditions. Moreover, marking could change the subsequent behavior

of tadpoles and make them more susceptible to disease or predation in the field (i.e. reduce their survivorship under field conditions). A field study may therefore be able to conclude on the use of VI Alpha tag for *A. obstetricans* tadpoles marking.

Acknowledgments.—This work was supported by grants from the BiodivERsA project RACE (Risk Assessment of Chytridiomycosis to European amphibian biodiversity; www.bd-maps.eu). We also thank Pieter Matthieu for help with the experiment. Authors have complied with all applicable Animal Care guidelines, and all required French permits (capture permit and authorization for experimentation with animals) have been obtained. We thank one anonymous reviewer for useful comments on earlier version of this manuscript.

Using a Handheld PIT Scanner and Antenna System to Successfully Locate Terrestrially Overwintering Hatchling Turtles

The benefits of Passive Integrated Transponders (PIT) for identification of individual wildlife have been well documented. Originally used to determine movement of salmonids (Prentice and Park 1983), PIT technology has been used with a variety of reptiles and amphibians for spatial ecology studies. For example, mark-recapture techniques were used in conjunction with PITs to measure habitat use and movement of Brown Water Snakes (*Nerodia taxispilota*; Mills et al. 1995) and the activity patterns of arboreal geckos (*Gehyra variegata*; Gruber 2004). PITs do not transmit a signal and cannot be located unless an antenna is within close proximity.

While earliest studies with PITs in turtles involved sea turtles, PIT injection into the body cavity of smaller freshwater adult turtles was not considered until Buhlmann and Tuberville (1998) injected young *Trachemys scripta elegans* with 12 × 2 mm PITs in

NEIL DUNCAN
Department of Biology, Hofstra University, Hempstead, New York, and American Museum of Natural History, 79th Street at Central Park West, New York, New York 10024, USA
e-mail: duncan@amnh.org

the inguinal region. Of six turtles recovered over two years, none showed adverse effects due to PITs. The authors recommend against the use of PIT with hatchling turtles, presumably due to the size of hatchlings relative to the tags used in their study. Subsequently, PITs (12 × 1 mm) were injected into the intraperitoneal region of hatchling *Chrysemys picta* with no adverse effects or mortality observed in the lab after one year (Rowe and Kelly 2005). A more recent study embedded PIT tags into *Podocnemis sextuberculata* and *P. unifilis* adults and hatchlings in the Amazon Basin (Guilhon et al. 2011). The authors reported results for mark-recapture, movement, abundance, survival, and recruitment.

I suggest a new application for using PIT tags with a scanner and a portable antenna to track and precisely locate terrestrial overwintering hatchling turtles. I field-tested this technique with hatchling Diamondback Terrapins (*Malaclemys terrapin*) overwintering beneath ground cover and soil. Diamondback Terrapin hatchlings overwinter on land near their nests but specific locations have not previously been determined (Muldoon and Burke 2012).

Methods.—In September and October 2009 I inserted 9 × 2.12 mm (0.067 g) PIT tags (Biomark, TX148511B) into 60 individual hatchling diamondback terrapins newly emerged from protected nests in Jamaica Bay Wildlife Refuge, New York. Thirty-six hatchlings were tagged in August, September, and October of 2010. An additional 251 hatchlings were tagged in August and September of 2011, all from protected nests at the same locale. Tag insertion generally followed the procedures of Rowe and Kelly (2005) with the exception that tags were not inserted via needle injection. Prior to tag insertion the skin in the left inguinal region was cleaned with 99% ethyl alcohol. A 2-3 mm incision was made into the body wall with a recurved scalpel blade to avoid excessive cutting of musculature and internal organs. A single sterilized PIT was inserted via the incision into the intraperitoneal region with sterilized tweezers. Once the PIT was no longer visible, the wound was again sterilized and covered with a quick-drying liquid bandage (CVS, liquid bandage). Hatchlings were observed a minimum of 20 min and up to 24 h post-insertion. Release sites were within 1 m of capture sites.

After release, area searches were conducted with a Biomark FS2001 Reader and portable antenna to determine each animal's location throughout the year. The reader was worn in a chest harness and the attached antenna was mounted on a handle and waved a few centimeters over or in direct contact with the ground much like a metal detector. Searches were generally concentrated on potential cover such as wrack lines, under dense vegetation and areas of leafy and woody debris. Failure to locate an individual was followed by a more methodical radius search from the release point.

According to the manufacturer, the antenna can scan through wood, soil, and water, although the signal is influenced by metals and other electronics and the read range of the antenna at highest power is optimal when a tag has a perpendicular orientation. The effective read range of the portable antenna with an 8-ft. (2.4 m) cable is 3.7 in. (9.4 cm) with the tag at a parallel orientation and 10.5 in. (26.7 cm) when the tag is oriented perpendicularly (Anonymous 2011).

Hibernacula were excavated to recover tags or possible hatchling remains after 1 June when presumably all active hatchlings had emerged. Excavation was done by hand. One millimeter of soil was removed from the site and scanned away from the nest to detect the presence or absence of tags. Each soil sample was carefully searched for any remains apart from the PIT tag.

Results.—One hundred forty-three (41%) of the tagged hatchlings were relocated at least once, 57 (16%) within 24 h. Of the individual hatchlings located, 127 (89%) stayed within 10 m of the nest while 13 (9%) moved 10–20 m, 1 (0.7%) moved 20-30 m, and 2 (1.3%) moved 40+ m, before settling in winter hibernacula. Thirteen individuals changed location at least one time before choosing hibernacula while one individual moved twice and three changed location three times.

I was able to monitor 81 (23%) hatchlings throughout the winter. By early summer they had either left their hibernacula or were killed by predators. Thirteen PIT tags were found when hibernacula were excavated, three with dead hatchlings and the other ten at varying depths in the soil without any visible hatchling remains.

Discussion.—I demonstrated the ability of the Biomark TX148511B scanner and handheld antenna to locate PIT-tagged hatchlings within their shallow hibernacula in a terrestrial environment under a variety of soil types and moisture conditions and the ability of hatchlings to retain the PITs for up to 295 days. Previous studies imbedded larger 12 × 2 mm PIT tags (Buhlmann and Tuberville 1998) or 10 × 2.1 mm tags (Camper and Dixon 1988) into turtles. The smaller 9 × 2.2 mm tag allowed me to embed tags into hatchling turtles, apparently without negative effects, although I cannot identify the cause of deaths for some tracked turtles.

The finding that 59% of tagged individuals were never relocated and 77% were lost before spring emergence may be attributed to five possibilities. Hatchlings may have moved beyond my search area, either on land or into the ocean. Thick vegetation hampered effective searching, either by making some areas impassable to me or by deflecting the antenna from effectively scanning some areas. Hatchlings may have dug deeper than the effective read range of the antenna. Also, marked hatchlings may have been killed by predators and carried away. Tags found with no visible hatchling remains were possibly shed from live individuals.

Compared to a radio-telemetry system, the PIT tag system is less expensive per animal (ca. US $6.25/ tag vs. ca. US $200/ transmitter) but more expensive for receivers and antennas (ca. US $4500 vs. ca. US $1200). Marking a large number of hatchlings, especially given normally high predation rates, is prohibitively expensive with radio transmitters, but may be possible with PIT tags. PIT tags are smaller and lighter than radio transmitters (0.067 g vs. 0.23 g) which may be important if attachment weight may alter the behavior of tagged animals. Adhesives for transmitters may affect normal shell growth in young turtles and the recommended transmitter weight is not more than 10% of the host animal (Beaupre et al. 2004). The average weight of terrapin hatchlings in Jamaica Bay is 6.7 g (N = 74). Small radio transmitters typically having lifespans of days to weeks are a viable option for short-term tracking studies. However, PIT tags weighing 1% of the host hatchling have indefinite lifespans, perhaps making it possible to track hatchlings into maturity. Unlike radio transmitters, PIT tags can only be detected from a small range. A distinct disadvantage of the handheld antenna is the potential need for a researcher to search large areas that may be covered by thick vegetation. It is also possible to confirm predation on PIT-tagged animals via the presence of tags in predator scats because PIT tags should survive predation events. Known latrine sites as well as individual scats can be scanned for tags, which would indicate predation events.

There is little information regarding behavior for the young of many reptiles. This is especially true with *Malaclemys* and *Terrapene* hatchlings, both of which have been reported to overwinter on land (Capitano 2005; Draud et al. 2004). Therefore, identification of critical habitat for both terrestrial and aquatic turtles that may overwinter on land is necessary for direct effective management.

Acknowledgments.—I thank Biomark for generously loaning equipment for the field trial and The National Park Service Jamaica Bay Institute, American Museum of Natural History Lerner Gray Fund for Marine Research, and the South Shore Audubon Society for financial support. Russell Burke, Alex Kanoniak, Ceasar Rahman, and the diamondback terrapin research team collected hatchlings and aided in tagging.

Sex Identification in the Common Snapping Turtle (*Chelydra serpentina*): A New Technique and Evaluation of Previous Methods

The Common Snapping Turtle has been regarded as a species of conservation concern and is very susceptible to declines (Brooks et al. 1991; Congdon et al. 1994; Tucker and Lamer 2004), primarily due to life-history constraints and documented imbalances in sex ratio (Congdon et al. 1994; Steen et al. 2006; Steyermark et al. 2008). Populations have been negatively affected by a variety of mortality sources, including female road mortality (Steen et al. 2006), overharvest (Congdon et al. 1994; Garber and Burger 1995; Mitchell 1994; Steen and Gibbs 2004; Tucker and Lamer 2004), and global warming (Tucker et al. 2008), all of which may impact sex ratios.

Although studies of snapping turtle demography are important for their conservation and management, gender assignment methods vary in their reliability. Morphological ratios have been developed (M. Dorcas, unpubl. data; Ernst et al. 1994; J. Tucker, pers. comm.) but differ substantially from one another and are not always accurate (pers. obs.). Sexual size dimorphism has also been used to differentiate between sexes, as male snapping turtles typically grow larger than females (Gibbons and Lovich 1990; Mitchell 1994; Palmer and Braswell 1995), but this attribute cannot be used on turtles that are not full-grown adults. Several sources (Ernst et al. 1994; Johnson 2000; Mitchell 1994; Palmer and Braswell 1995; Phillips et al. 1999) also note that males have a longer precloacal tail length than females but this measure is relative to the turtle as the precloacal lengths of younger turtles change throughout development (Gibbons and Lovich 1990).

Penis extrusion has been reported in males in response to handling and suggested as a potential aid when attempting to determine sex of male snapping turtles (de Solla et al. 2001). The present study details a simple and accurate sexing method for Common Snapping Turtles that relies on extrusion of either the penis by males or the cloacal wall by females. Using this technique, I tested the accuracy of previous methods used in sex determination. Besides providing an accurate analysis of sex ratios in this species, this method will also allow researchers to accurately sex snapping turtles in future studies and provide a mechanism to reevaluate previous studies involving sex determination.

EMILY A. DUSTMAN
Department of Biological Sciences, Murray State University, Murray, Kentucky 42071, USA
e-mail: emily.dustman@gmail.com

Methods.—Turtles were sampled during the summers of 2008 and 2009. In 2008, turtles were sampled at Carlyle Lake in Illinois (USA), approximately 150 km upstream of the confluence of the Mississippi and Ohio Rivers. The lake was constructed by the United States Army Corps of Engineers (USACE) in the 1960s for the purpose of flood control, human recreation, and as a water supply (X. Potts, pers. comm.). Study sites were located at North Carlyle in Fayette Co. (38.8333°N, 89.1833°W), managed by the Illinois Department of Natural Resources; South Shore (38.6166°N, 89.2833°W), located in Clinton Co., managed by the USACE; and Coles Creek (38.6500°N, 89.2666°'W), also located in Clinton Co. and managed by the USACE.

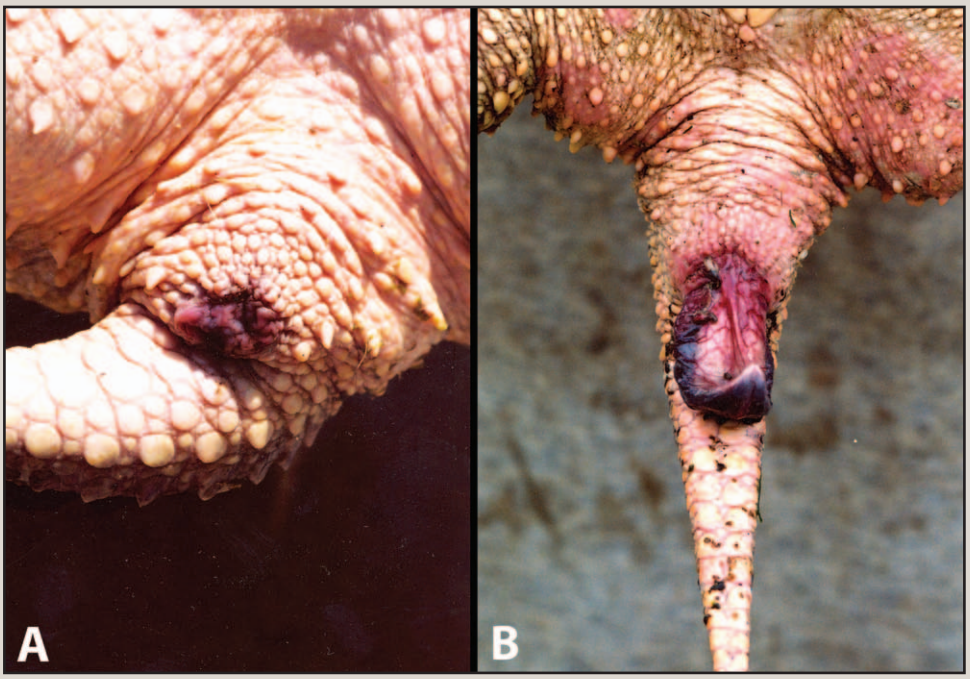

FIG. 1. Photo representation of snapping turtle genitalia (A, female cloacal wall; B, male penis) when using the eversion technique.

In the summer of 2009, my study continued at and near the Clear Creek Wildlife Management Area (CCWMA) in Hopkins Co., Kentucky. Sites in Kentucky were the Cabin site (37.3500°N, 87.7166°W), owned by a private landowner and outside of the CCWMA; Downstream (37.3333°N, 87.6833°W), managed by the Kentucky Division of Fish and Wildlife Resources (KDFWR); and Upstream (37.3166°N, 87.6666°W), also managed by the KDFWR as part of the CCWMA.

Turtles were collected using hoop nets (Legler 1960) that were 1.5 m in length and 76 cm in diameter and were made with 2.5-cm nylon mesh. During the trapping period, nets were baited daily with fresh fish carcasses and once weekly with canned sardines in soy oil (Vogt 1980). At the Illinois site, eight hoop traps were checked daily for a total of 240 trap days. At the Kentucky study site, six hoop traps were checked daily for a total of 270 trap days.

Measurements taken on all captured turtles with Haglöf calipers to the nearest 1 mm consisted of carapace length, carapace width, carapace height, plastron length, posterior lobe length, and precloacal length. Posterior lobe was measured from the middle of the plastron to the posterior end of the plastron. Precloacal length was measured from the posterior end of the plastron to the center of the cloaca (Ernst et al. 1994). Each turtle was weighed on a spring platform scale to the nearest 10 g and given a unique mark along the marginal scutes (Cagle 1939).

Collected snapping turtles were evaluated with several methods of sex determination. The new method presented here, the eversion technique, involves holding the turtle by the lower marginal scutes beneath the rear legs with the plastron facing away, approximately 30 centimeters from the holder's body in a vertical position. Once properly positioned, the holder then motions the turtle gently up and down, tilting slightly until the penis or the cloacal wall is everted (Fig. 1). In addition to this sexing technique, the ratio of the posterior lobe length to precloacal length, referred to as PPR (Fig. 2), was also utilized to sex snapping turtles. The ratio does not apply to turtles <200 mm in carapace length (CL), however, which are considered sexually immature (Ernst et al. 1994). As a result, I also evaluated the ability of the eversion technique to assess sex in turtles ranging from 100 to 200 mm CL.

According to Ernst et al. (1994), a turtle is considered male if the ratio between the precloacal length and posterior lobe (precloacal length divided by posterior lobe) is greater than 1.20 and is considered female if this ratio is less than 1.10. Conversely, Dorcas (unpubl. data) suggested that if the ratio between precloacal length and posterior lobe is greater than 0.86 the turtle is considered male and less than 0.86 the turtle is considered female. Furthermore, Tucker (pers. comm.) considered a turtle a male when the ratio is greater than 1 and female when the ratio is equal to or less than 1. These morphological ratios were tested for accuracy with turtles of known sex, which was determined by using the eversion technique.

Analyses were performed using the statistical program R (R Foundation for Statistical Computing, Vienna, Austria). A contingency table was created to determine how many times sex was correctly or incorrectly assigned. In order to establish whether previous methods for sexing were significantly different from one another, a Pearson's Chi-square test was performed (α = 0.05).

Results.—A total of 215 Common Snapping Turtles were collected during this study. Nearly all specimens (98%, N = 210/215) everted a cloacal wall or penis. Everted male genitalia varied in color from light gray to shades of pink and purple and typically had a smooth texture. Everted cloacal walls of females also varied in these colors and were also smooth in texture (Fig. 1). When the eversion technique was applied to turtles classified as juvenile (< 200 mm CL), 13 of the 16 turtles everted their genitalia.

Ernst et al.'s (1994) morphological ratio (PPR > 1.20 = male and PPR < 1.10 = female) was 67% accurate when tested against turtles of known sex with 72 known males misidentified. Tucker's method (PPR > 1.0 = male and PPR < 1.0 = female) was 88% accurate with 23 known males and 4 known females being misidentified

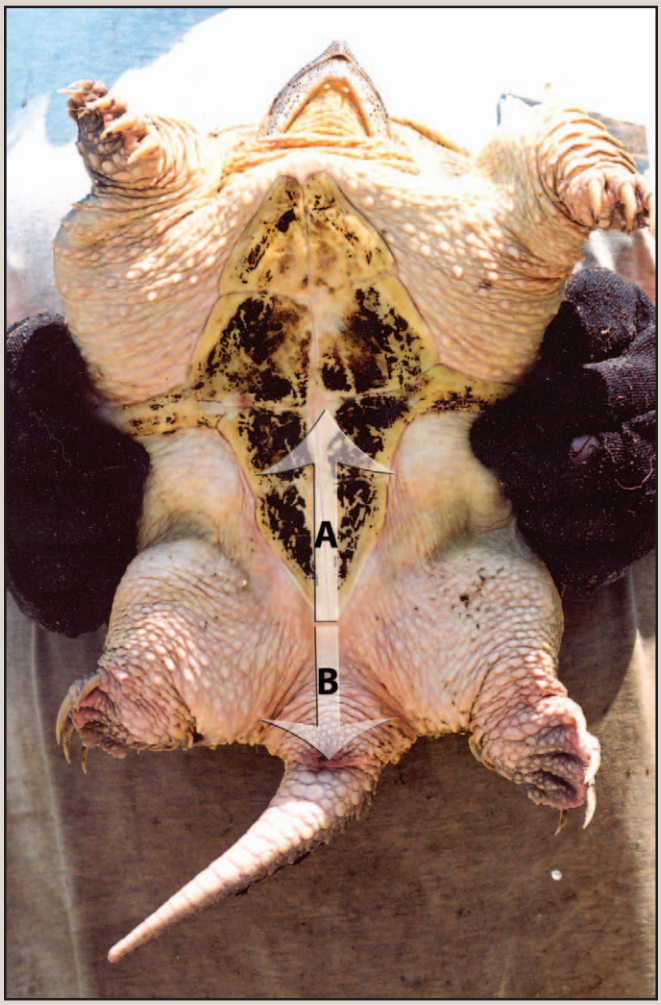

FIG. 2. Photo representation of measurements used in calculation of PPR as B divided by A (A, posterior lobe; B, precloacal length).

by this ratio. Dorcas's method (PPR > 0.86 = male and PPR < 0.86 = female) was 92% accurate with 4 known males and 14 known females misidentified. As verified by the eversion technique, the latter two ratio methods were both significantly more accurate (Dorcas: $\chi^2 = 20.5$, df = 1, $P < 0.0001$, N = 215; Tucker: $\chi^2 = 14.71$, df =1, P = 0.0001, N = 215) than the Ernst et al. ratio (N = 202). The Tucker and Dorcas methods did not differ significantly in accuracy ($\chi^2 = 0.56$, df = 1, p = 0.46). The PPR ranges were broadly overlapping for males (0.66–1.91; mean 1.16) and females (0.31–1.10; mean 0.73), with 73 males (51% of the total sample of males) having higher ratios than any of the females, i.e., almost half of the males overlapped with females in PPR ratio.

Discussion.—I present a simple, safe, and unambiguous method for sexing snapping turtles. Only 5 of 215 specimens could not be unambiguously sexed using this technique, one of which was clearly in poor health (it was lethargic, had numerous tumor-like growths, and was found dead the next day) and three that were very small juveniles. Previous methods that rely upon morphological ratios had low accuracy rates when tested against the results of the eversion technique, as the most accurate unpublished method of the three still misidentified gender 8% of the time. Furthermore, despite the varying accuracy of these three developed morphological ratios, the PPR ranges were 0.66–1.91 mm for males and 0.31–1.10 mm for females, thus illustrating that there actually is no ideal morphological ratio for determining snapping turtle gender. Future studies would thus benefit from utilizing the eversion method described here rather than any of the current morphological ratios.

There are several other problems with using morphological ratios. For the most commonly used method (Ernst et al. 1994), there is a gap in the ratio in which turtle sex is unknown. Turtles with a PPR greater than 1.20 are assumed to be male and turtles with a PPR less than 1.10 are assumed to be female but for any turtle with a PPR falling between 1.11 and 1.19, sex is unknown (Ernst et al. 1994). In addition, it is likely that these ratios will not be equally accurate across the entire geographic range of snapping turtles. Several other turtle species have been known to exhibit differences in morphology, color, shell shape, and body size depending on geographic location (Iverson 1985; Lovich et al. 1998; Tinkle 1961), perhaps as a result of physiological or environmental differences (Gibbons and Lovich 1990). Further, it has been noted that precloacal length increases throughout development in most, if not all, turtle species (Gibbons and Lovich 1990). In addition, chemical contaminants can affect the morphological development of sexual characteristics, particularly reducing the rate of increase in precloacal length. For instance, in areas with organochloride contamination, the PPR's of male snapping turtles were significantly smaller than those from non-contaminated sites (de Solla et al. 1998). To this end, assigning sex based on morphological ratios can potentially lead to skewed demographic data. Furthermore, past studies that have utilized these morphological ratios excluded turtles < 200 mm CL (Ernst et al. 1994 and J. Tucker, pers. comm.). In contrast, 13 of 16 turtles smaller than this size were successfully sexed using the eversion technique. Thus, the eversion technique can be successfully used for some juvenile common snapping turtles with a CL between 100 and 200 mm (see also de Solla et al. 2001), whereas the ratio techniques cannot.

With this new sexing method, assigning sex to Common Snapping Turtles is unambiguous and 100% accurate if the turtle everts its genitalia; only 1% of adults failed to do so. In the past, the only definite way to determine sex of the Common Snapping Turtle was through dissection, which involved killing the specimen. The nonlethal eversion technique is thus especially beneficial to snapping turtle populations where they are a species of conservation concern.

The ability of biologists to accurately record sex is important for the management of many populations, but particularly turtles in which much of the female-biased mortality is a direct result of anthropogenic impacts via road mortality (Haxton 2000; Marchand and Litvaitis 2004; Steen et al. 2006). The development of the eversion sexing technique is important for the conservation of snapping turtles and may allow more accurate management decisions to be made in the future. Further development of this and other techniques, particularly in other species of turtles with more pressing conservation needs, will only aid in the management of such populations.

Acknowledgments.—I would like to thank the following individuals and institutions for their help and support during this study: Howard Whiteman, Christopher Mecklin, Claire Fuller, and Ed Zimmerer (Murray State University); Bob Hammel and Gary Tatham (Illinois Department of Natural Resources); Dick Conner and Kimberly Hammel (USACE); Eric Williams (KDFWR); Jane Benson (MidAmerica Remote Sensing Center); Lake City Fish Market; and John Dustman, Amy Krzton-Presson, Brett Davis, Todd Levine, Michelle Mirowski, and John Hewlett.

DNA Extraction from the Fecal Sac of Common Chameleons, *Chamaeleo chameleon*

Genetic tagging facilitates studies of species identification, analysis of population size and structure and the tracking of individuals. Because the sampling of natural populations of vertebrates for molecular ecology studies often involves the injuring or the sacrificing of individuals, this inevitably interferes with their natural behavior. Non-invasive, DNA-based techniques have become routine in assessing population abundance and genetic structure (Banks et al. 2003; Paetkau 2003; Palomares et al. 2002). Such techniques include buccal swabbing (Beebee 2008; Poschadel and Möller 2004), external eggshell swabs (Schmaltz et al. 2006) and fecal DNA extraction (Wasser et al. 1997). DNA from feces provides an ideal, non-invasive, source of information. This is especially so because feces are readily available and abundant and because even minute amounts of feces contain large quantities of the animal's DNA (Wasser et al. 1997). Consequently, fecal remains of free ranging animals have been used extensively in mammalian (Adams et al. 2007; Broquet and Petit 2004; Ernest et al. 2000; Frantzen et al. 1998) and avian (Idaghdour et al. 2003; Regnaut et al. 2006) research. However, feces were only infrequently used in reptilian research and only fresh samples, immediately cooled, have yielded PCR products (Jones et al. 2008). We here examined, for the first time, the use of

fresh and of old fecal mucous sacs of the Common Chameleon, *Chamaeleo chameleon* (Reptilia, Lacertilia) as sources for DNA sampling that is non-invasive and has no adverse effects.

Common Chameleons are arboreal lizards that forage for insect prey and dispose of their feces wrapped in a mucous sac. The sac is formed in the intestine and contains the chameleon's epithelial cells. We addressed the following questions: 1) Does DNA from the fecal sac reliably represent the endogenous DNA of the chameleon? 2) Can DNA extracted from the fecal sac be used for PCR reactions? 3) Does the quality and/or quantity of the DNA, extracted from dry samples of different age, change over time?

Chameleons were collected in northern Israel and kept in captivity (details in Lustig et al. 2012). The following samples were obtained: a) liver tissue (N = 3); b) tail tip tissue (N = 5); c) buccal swabbing (N = 13); d) fresh feces (N = 23) (Fig. 1B); and e) dry feces of different ages (up to 43 days; N = 69) (Fig. 1A). Liver and tail tip tissues were collected from dead individuals and kept frozen at -20°C. To obtain buccal swabs, a pipette tip was gently moved over the chameleons' gums and the samples then washed off the tip using ATL lysis buffer (QIAGEN). Fresh feces were collected on the day of excretion and kept in distilled water at 4°C for a few days until extraction, to prevent the mucous sac from drying. Dry feces were collected over a period of 43 days and were kept in open, dry Petri dishes, in an open outdoor container placed in a shed. The container was covered with gauze so that the samples were protected from insects yet exposed to ambient Mediterranean summer conditions (temperatures of ca. 28–32°C and humidity of ca. 80–90%). Prior to DNA extraction, a fecal sac was removed from the fresh or the dry sample using tweezers, and washed with distilled water. Extractions were performed using DNeasy Blood & Tissue Kit (QIAGEN) following the manufacturer's instructions. The DNA quantity of each sample was assessed by Nano-Drop and its integrity was checked by agarose gel electrophoresis.

To validate the extraction of chameleons' high molecular weight DNA from the fecal sacs, we amplified and sequenced fragments of the mitochondrial Cytochrome C Oxidase I (COI) gene (NCBI GenBank Accession #ABM89788). The following primer pairs were used for the amplification: COI.F1 (5'- AGGCGGAGATCCCGTACTAT-3') and COI.R1 (5'- GAAATAGGCTCGGGTGTCAA -3') fragment size 244 bp; COI.F2 (5'- TCTATTGATTTCCACTAATTTCAGG -3') and COI.R2 (5'- GAATATCGTCGTGGTATTCC -3') fragment size 181 bp.

DNA amplification was performed at 94°C for 4 min and subsequent 35 cycles of 94°C for 1 min, 57°C for 1 min, 72°C for 2 min, with a final extension of 72°C for 4 min. Each PCR reaction contained: 9µl Taq Polymerase (Lamda Biotech©), 0.7µl $MgCl_2$, 4.3µl H_20, 1µl primer F (10 mM), 1µl primer R (10 mM) and 2µl DNA. The single PCR products were purified (QIAGEN, QIAquick PCR Purification Kit) and sent to ex-campus sequencing. Sequence chromatographs were checked manually, and compared with the *C. chameleon* COI sequences in the GeneBank.

A high quantity of DNA was obtained from the liver and the tail tip samples, a lower quantity was obtained from the fresh and the dry mucous fecal sac, and a significantly lower amount from the buccal swabbing samples (Fig. 2A).

The sequence results from all the tested tissues confirmed that the DNA extracted and amplified was the endogenous DNA of the chameleons. The quality of the sequences from both the fresh and the dry fecal sacs at different ages was similar (Fig. 3). Our samples showed a complete (100%) identity with the COI sequence of the mitochondrial genome published for the common chameleon (NCBI GenBank Accession #EF222198). A sequence comparison of a fragment of 240 bp from the COI gene of nine individuals showed no variation.

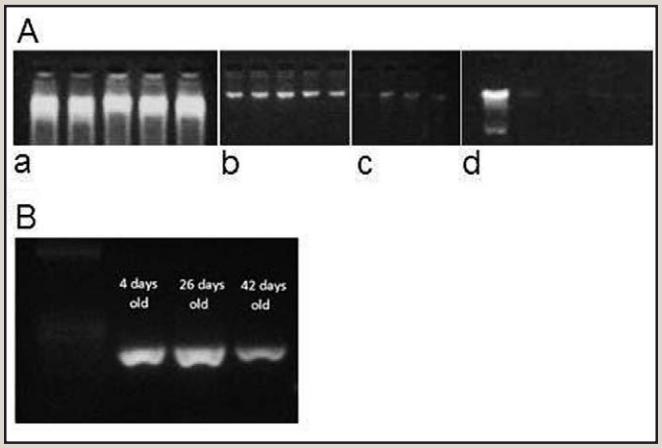

FIG. 2. A) High molecular weight genomic DNA isolated from: a) tail tip; b) fresh fecal sac; c) dry sac; d) buccal swabbing. B) COI PCR products from dry feces samples after 4, 26, and 42 days in natural climatic conditions.

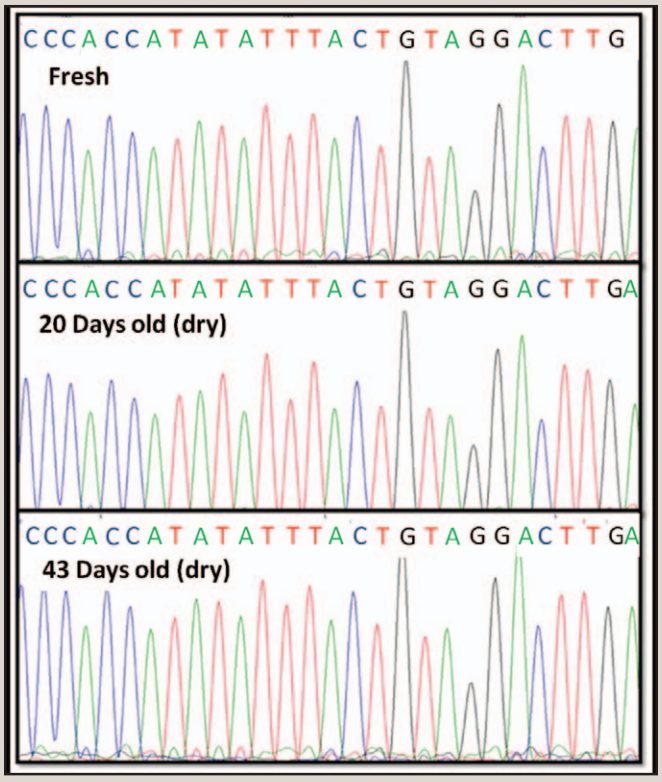

FIG. 3. COI gene sequence extracted from mucous sacs at different ages.

Techniques using DNA to distinguish between species, populations, and individuals are of extremely high value in molecular ecology. However, the reliability of these measurements depends not only on the genetic material but also on having a large sample size to characterize any population variation. The difficulty of acquiring adequate sample sizes using invasive techniques, such as tissue or blood sampling, restrict the application of molecular technology in the field (Wasser et al. 1997). Non-invasive samples such as sampling of hair, urine, saliva, feathers, scent marks, eggshells, sloughed skin, and feces have been found to be effective in acquiring DNA from free-moving animals (Beja-Pereira et al. 2009). However, non-invasive sampling methods for reptiles have been largely overlooked, probably because of the difficulty in identifying the remains. Most non-invasive samples from reptiles depend on sloughed skin, aborted eggs, road-kill, and museum samples. Such samples may well be biased and may not necessarily represent the actual population structure. Feces, however, are commonly used as a DNA source for avian and mammalian species because they provide more information (e.g., on diet, stress or reproductive hormone status) and thus should be useful in herpetological studies as well (Beja-Pereira et al. 2009; Jones et al. 2008).

For reptiles and amphibians that produce a fecal sac, we present here a non-invasive technique of high potential for species-specific sampling. Our results clearly demonstrate that sufficient amounts of high molecular weight DNA may be obtained from the fecal mucous sac (Fig. 2A). Moreover, fecal sacs remained a good source for DNA extraction and PCR amplification for over a month following their secretion, under natural environmental conditions (Fig. 2B).

The sampling of mucous sacs requires no animal handling and thus imposes no disturbance, and may have wide applications for population genetics in the field. The ability to isolate DNA of high molecular weight from old and dry fecal sacs makes this method especially appealing.

Acknowledgments.—We wish to express our thanks to the anonymous referees for their helpful comments. The research was supported by the Israel Science Foundation (ISF) to GK and conducted under permits of the Israeli Nature and Parks Authority (# 2011/11411). We deeply thank Yossi Baydatch and the staff of University of Haifa - Oranim for their help.

Positioning Minnow Traps in Wetlands to Avoid Accidental Deaths of Frogs

Funnel trapping has become a widely used technique for monitoring amphibians and can be especially useful for sampling species that congregate at breeding wetlands for short periods of time (Willson and Gibbons 2010). While this technique can provide invaluable information on the biology of the species of interest, inherent risks associated can sometime lead to the injury or even death of the organism being sampled.

While surveying wetlands for breeding Crawfish Frogs (*Lithobates areolatus*) using collapsible mesh minnow traps, we found one adult female nearly drowned because her leg was caught at the knee in the metal support structure of the trap. The minnow traps we used were manufactured by American Maple Inc. (Gardena, California) and sold by Lee Lures (Valrico, Florida; product # TR-503). Traps were 61 cm x 30 cm, covered with black polyethylene mesh (mesh size 1.5 x 1.0 cm; Fig. 1a). The mesh is supported by a steel framework of a single piece of 0.4 cm (diameter) stock twisted to form two end loops (30 cm diameter) and a coil frame (61 cm) with 3½ spirals between trap ends supporting the mesh. Where the coil portion of the frame attaches to the end loop the distance between the metal stock gets progressively smaller (Fig. 1b). The trap mesh has two zippered openings, one, 25 cm long, allowing access to the trap, and a second, 11 cm long, at the opposite side accessing a bait pouch. The large opening is situated at the opposite side of the trap from where the coil of the metal frame attaches to each end loop, therefore, when the opening is positioned up and out of the water, these frame attachments are submerged.

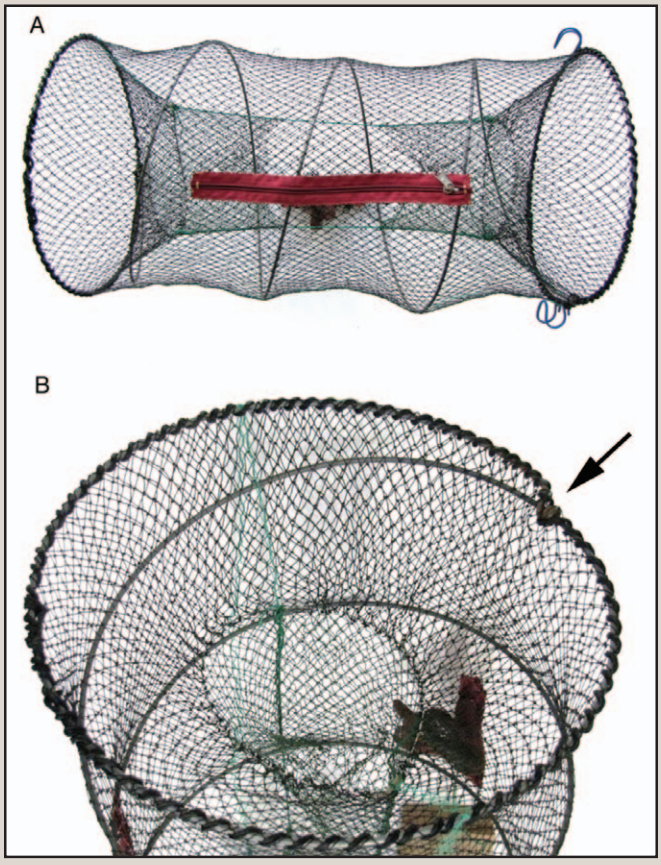

FIG. 1. Collapsible mesh minnow trap used to census Crawfish Frogs. A) Top-down view of the trap with access zipper positioned on top. B) View of the trap opening showing the steel coil and end loop junction where a frog's leg can be caught.

On 15 March 2012, we discovered a female Crawfish Frog (8.8 cm SVL, 86 g) in one of our traps. The left leg of the frog was caught immediately above the knee in the trap frame between the spiral and the end loop. There was no visible trauma to the leg, but the frog appeared to have been submerged for some time (the trap was last checked the previous day) and was unconscious; it was not breathing and had no detectable heartbeat. Crawfish Frogs are atypical ranids in that they do not tolerate submergence for long (~ 1 h) periods of time (Heemeyer and Lannoo 2010, 2011). Soon after chest massage we noticed a heartbeat, and after approximately 20 minutes, the frog began breathing on its own and was brought into our lab for recovery and observation. Though initially lethargic and unresponsive, later in the day the frog appeared healthier (sitting upright, conscious) and three days later, on 18 March, we released her near where she was captured. On 20 March she was found dead in shallow water at the release site, mostly intact, but with lacerations on her throat and abdomen. Because the frog was found in the open, close to the point of release, we suspect that it may have suffered neurological damage while it was submerged in the trap, and that its ability to quickly escape predation was compromised. It is also possible that the frog succumbed to its injuries and was attacked but not consumed after it had already died.

Accidental trap injury and mortality have been reported for other herpetofauna including Greater Sirens (*Siren lacertina*; Johnson and Barichivich 2004), Two-toed Amphiumas (*Amphiuma means*; Darby et al. 2001), Florida Green Watersnakes (*Nerodia floridana*; Johnson and Barichivich 2004; Darby et al. 2001), Diamond-backed Terrapins (*Malaclemys terrapin*; Dorcas et al. 2007; Grosse et al. 2009), False Map Turtles (*Graptemys pseudogeographica*), Pond Sliders (*Trachemys scripta*), Smooth Softshells (*Apalone mutica*), Spiny Softshells (*Apalone spinifera*), and Snapping Turtles (*Chelydra serpentina*; Barko et al. 2004). In an effort to prevent injury and accidental drowning, researchers have augmented trap designs by attaching floatation devices (Casazza et al. 2000), using plastic coated mesh (Johnson and

Barichivich 2004), and extending trap cages above the water surface (Roosenburg et al. 1997).

Trap mortality is not often reported in field studies (Enge 2001), and most available funnel trap mortality data for amphibians are from studies using terrestrial funnel trapping techniques. Enge (1998) reported an anuran trap mortality rate of 7.8% when using a combination of aquatic and terrestrial funnel traps, and studies using exclusively terrestrial funnel traps have reported anuran mortality rates ranging from 0.9–37.1% (Enge 2001; Jenkins et al. 2003). In our study we have repeatedly sampled three different wetlands during four different breeding seasons, and in this time have observed relatively low trap-related mortality (1.0%; 2/194 adults captured) in breeding Crawfish Frogs. The only other Crawfish Frog death occurred when an adult male was skinned and eviscerated by a predator (likely either a mink or raccoon; Heemeyer et al. 2010) within a trap. What is particularly unfortunate about the incident we report here is that Crawfish Frogs are listed as Near Threatened on the IUCN Red List (IUCN 2012) and are a state endangered species in Indiana where our study was located (Engbrecht and Lannoo 2010). Because the female was gravid, we estimate, based on size, that she would have produced approximately 4,200 eggs (C.I. ± 410; Kinney 2011; Redmer 2000). While we have not observed this type of trap entanglement in any other species during our study, the inherent risk seems present.

When sampling for Crawfish Frogs at our study site, we always place funnel traps in shallow water with the top portion of the trap above the water's surface, which allows frogs and other terrestrial animals to surface for air. Because of the current construction of the American Maple Inc. collapsible mesh minnow traps, we recommend that care be taken to place the spiral attachments of the frame to the end loops out of the water to prevent casualty. This means that the access zipper is submerged and—depending on water level—that the bait pouch is out of the water. This would not be a problem for unbaited traps, but would be an issue if using submerged bait. We have notified the manufacturer of this issue, and suggested during construction that they rotate the mesh on the frame, so that the attachments of the spiral to the end loops is aligned with the access zipper instead of the bait pouch.

Acknowledgments.—We thank Katie Smith, Ron Ronk, and Brad Feaster for their support and for access to our study site. Special thanks to Rochelle Stiles for assistance with Fig. 1. This project was supported by State Wildlife Grant (SWIG) Number E2-08-WDS13 awarded by the Indiana Department of Natural Resources. Research was performed under Institutional Animal Care and Use Committee (IACUC) number 3-24-2008 and DNR permit number 12-0015.

Attachment and Deployment of Remote Video/Audio Recording Devices (Crittercams) on wild American Alligators (*Alligator mississippiensis*)

Historically, researchers have used direct observation, often with the assistance of specialized equipment (e.g., binoculars, telescopes, remote video/audio recorders), to document animal behavior and ecology (Altmann 1974). However, these observer-based techniques typically cause disturbance to animals via presence of observers or equipment, are limited in the data that can be collected (e.g., field of view, magnification), and often occur over short temporal scales, all of which restrict the inferences that can be gleaned from the data (Marsh and Hanlon 2004; Samuel et al. 1987). Documenting the behavior of aquatic species, such as crocodilians, presents additional complications because the majority of their interactions occur below the water's surface where direct observation can be even more challenging (Dickens et al. 2011). To overcome these limitations and increase the quality and quantity of observational data, researchers have utilized technological advances to develop devices that can be attached to animals and are capable of collecting video and audio data from the animal's point-of-view. Collectively known as "animal-borne imagery," this field has flourished in the past 20 years, in-part due to the success of the National Geographic Remote Imaging (NGRI) Crittercam program (Marshall 1998). To date, their animal-borne imaging systems have been used to study the behavior of over 60 species spanning a wide range including aquatic vertebrates and invertebrates, such as large sharks, sea turtles, and Humboldt squid, as well as terrestrial species such as lions, bears, and various species of birds (Marshall, unpubl. data). Crittercam, in addition to other animal-borne imaging systems, has revolutionized the field of animal behavior and ecology by permitting the observation of novel natural history characteristics, such as cryptic foraging behaviors or subtle species interactions, and by expanding the range of response variables available for ecological studies, such as diving, foraging, and prey capture success rates (Moll et al. 2007).

To facilitate use of animal-borne imaging to study crocodilians, initial experiments were conducted with Crittercam units on crocodilians in 1988 and later in 2004. Variations on a neoprene-and-nylon webbing style harness were used to attach a video recorder to captive *Alligator mississippiensis* (American Alligator) and in 2001 test fittings were done with *Gavialis gangeticus* (Indian Gharial), although planned wild deployments were not carried out. Attempting to design an attachment apparatus that could securely hold the Crittercam during deployment but also incorporated a reliable, automatically-activated releasing mechanism led to development of fairly complex harnesses that were difficult to make and deploy. Here we present a much simpler method for attaching and detaching Crittercam units on crocodilians that has proven successful and we summarize the results from our first deployments on wild adult *A. mississippiensis* in two Florida estuaries.

Methods and Materials— From 22 April to 6 May 2010 and 27 April to 8 May 2011, adult (> 2 m total length, TL) *A. mississippiensis* were captured using standard crocodilian capture techniques (e.g., snatch hooks and rope snares) as part of ongoing research and monitoring programs. Once secured, individuals were subject to standard morphometric measurements (head length, head width, snout-to-vent length, total length, and tail girth), blood sampling, scute tissue biopsies, and urine collection. Individual alligators were held for 20–30 minutes during sampling and Crittercam unit attachment and then immediately released at their sites of capture. The location of individual alligators outfitted with a Crittercam unit was monitored via an onboard VHF radio transmitter throughout the duration of each deployment.

Crittercam units were loaned by NGRI for two weeks during each sampling period. Each cylindrical Crittercam unit (5.7 cm height × 27 cm length, 770 g) was secured using two worm gear hose clamps (10 cm max. diameter) to a composite base (32 × 10 cm, 350 g), hereafter known as the cradle, constructed out of a thin (3 mm thickness) carbon-fiber base-plate and buoyant polyurethane foam body, formed to accommodate the Crittercam unit (Fig. 1A). Once mounted to the cradle, the Crittercam footprint measured 32 × 10 × 7.5 cm and weighed 1 kg (Fig. 1B). Additionally, to reduce vibration, adjust the field of view, and add stability, we fixed a single piece of 5-cm-thick heavy-duty urethane foam cut to dimensions of the cradle (0.78 g/cm^2, Airtex Industries Inc., Houston, Texas) to the bottom of the cradle using hot glue.

Crittercam units were attached to alligators using a harness constructed from a single (1–2 m) length (size varied depending on girth of individual) of 2.52 cm wide 100% cotton webbing (National Webbing Products Co., Plainview, New York; Fig. 2). To allow for full mobility of the head and neck we positioned the Crittercam unit foam side down on the dorsum of the alligator so that the anterior edge of the cradle rested above the anterior edge of the shoulder girdle. The middle of the length of cotton webbing was laid through a channel at the anterior edge of the cradle base-plate, between the raised polyurethane form and two protruding bolts (1 cm in height) at the leading edge. The two free ends of the cotton webbing under the ventral surface of

the alligator at the shoulder girdle and opposing ends secured to a single plastic zip-tie (22.6 kg test) via two 2.5-cm steel quick-links at the posterior of the base-plate of the cradle (Fig. 2). We adjusted each harness to accommodate body size variation by looping the terminal end of the cotton webbing through a 2.5-cm flat metal slide. This loop also served to secure the quick-links in place (Fig. 2 A). To allow for programmed detachment, the plastic zip-tie holding the terminal ends of the harness was fed through a portal (0.5 cm diameter) in the base-plate of the cradle then through a circular tube drilled into a rectangular polyoxymethylene (Delrin; DuPont, Washington D.C.) housing (5.4 × 1.9 × 1.2 cm) attached to the base-plate (Fig. 2B). Prior to attachment, within the plastic housing a flattened brass bolt was screwed in a perpendicular tube so the flattened end was flush with the anterior edge of the tube containing the plastic zip-tie to act as a backstop. Following the placement of the zip-tie, a 1-cm-long steel blade (flat on one side and roughly sharpened on the other) was inserted into a portal at the posterior end of the perpendicular tube, held in place by a rubber padded screw, and followed by a small pyrotechnic piston actuator (Chemring Energetic Devices, Downers Grove, Illinois) screwed into a threaded portion of the same portal (Fig. 2B). The actuator was then connected to a power port on the Crittercam unit and grounded to the rear faceplate of the unit using a small bolt. At the programmed time of detachment, an electrical impulse sent to the actuator via the power cord ignited a small amount of gunpowder housed in the actuator. The force from the ignited gunpowder then ejected a small piston from the anterior end of the actuator propelling the small cutting blade into the zip-tie, breaking the zip-tie as it contacted the brass backstop. Once the harness was detached, the Crittercam unit was free to float to the surface or fall on the ground depending on the habitat.

As a fail-safe, a Galvanic Timed Releases (GTR; Neptune Marine Products Inc. Port Townsend, Washington) was inserted between each quick-link and the zip-tie loop of the harness system (Fig. 2). Comprised of two dissimilar metals, GTRs corrode and separate at predictable rates dependent on their size and the salinity and temperature of the water in which they are used. We used two types of GTRs with predicted decay rates of either 24 or 48 h depending on the desired duration of each deployment. All portions of the harness system left in the environment (i.e., cotton webbing, quick links, metal strap slides, and GTRs) were biodegradable and in most cases, the harness was recovered with the Crittercam unit.

Crittercam units, depending on the camera type (standard or high-definition video), had the potential to record 6–8 h of audio and video data, constrained either by the capacity of the onboard batteries or the video data storage, depending on the sampling protocols used. The Crittercams can be programmed to sample the video according to a variety of time and environmental conditions, determined by the user. To maximize the coverage of the 24-h timeframe, we used a combination of 30- and 60-minute

Acceleration	Yes	No

*Observations are limited.

recording intervals over 4- to 8-h recording windows set at different times of the day. This enabled us to record over multiple days on the same individual and to collect data during all hours of the day. Crittercam units were deployed for one to two days under a variety of recording schedules including day and nighttime recording windows. To collect video at night, Crittercam units are outfitted with onboard red LED lights. Lights were programmed to turn on during nighttime recording intervals. In addition to audio and video recorders, Crittercam units also came outfitted with a variety of environmental data collection sensors, including temperature, depth, and acceleration. These data parameters were collected every second during deployments and data collection terminated at the scheduled time of detachment.

Results.—We outfitted 15 adult alligators (4 females and 11 males, TL range 221–307 cm, mean ± SD: 262 ± 25 cm) with Crittercam units (N = 9, at Merritt Island National Wildlife Reserve, 28.529543°N, 80.606585°W, in 2010 and N = 6, at Guana Tolomato Matanzas National Estuarine Research Reserve, 30.024833°N, 81.329628°W, in 2011; Fig. 3). Crittercam units were on average 1.9% of the total mass of an individual alligator (mean = 52 kg). A total of 102 hours of audio and video data was recorded during deployments, 79.5 h (~78%) of which was usable footage for behavioral analyses (i.e., clear view of surrounding habitat and the alligator's snout; Fig. 4). Four deployments ended early due either to units detaching prior to scheduled detachment (e.g., snagging on vegetation) or camera lenses becoming obstructed by vegetation and/or substrate. Only one individual displayed signs of discomfort or stress during deployments. That individual, a large male (224 cm TL), was missing a large portion (~40 cm) of its tail from a previous injury and seemed to be disoriented for a portion of the Crittercam deployment. We hypothesize this was due to the added weight and movement of the Crittercam unit in heavy wave conditions in deep water, combined with the loss of stabilization from the missing portion of the tail. In two instances alligators were located using VHF radio signals and the Crittercam unit was manually removed due to the detachment apparatus malfunctioning. Because in our study systems salinities were moderate to high (14–34 ppt) and ambient water temperatures were high (21–25°C), in addition to the fact that units were not fully submerged throughout deployments, GTRs corroded more slowly than anticipated: in 48 and 96 h for predicted 24- and 48-h models, respectively.

The 79.5 h of unobstructed video and audio data collected during deployments generated clear point-of-view footage in most environmental conditions encountered (Fig. 4). Given the properties of the camera (horizontal field of view: 114 degree for Gen 5.7 SD model and 170 degree for Gen 6.0 HD Crittercam) and its position on the alligator, the field of view encompassed the upper portion of the head, snout, and nostrils as well as the surrounding environment. In three instances the Crittercam and harness was displaced producing a side-angle image of the head and snout. Image clarity and field of view were negatively affected by water turbidity and aquatic vegetation density. In all conditions the movement of the head could be observed. We observed a variety of behaviors and species interactions and were able to record video footage during all times of the day and night, although the depth of view was reduced at night. Behaviors and interactions observed included inter- and intraspecific interactions, prey capture and pursuit, diving behavior, body position, basking patterns, and habitat use (Table 1).

Discussion.—Documenting and studying the behavioral interactions of living organisms, in particular aquatic species, can be difficult due to the constraints of technology, limitations of environmental conditions, and behavioral modifications brought on by the presence of human observers or equipment. To reduce bias and limitations in the study of animal behavior using observational techniques, researchers and technicians have developed animal-borne imagery as an effective means to

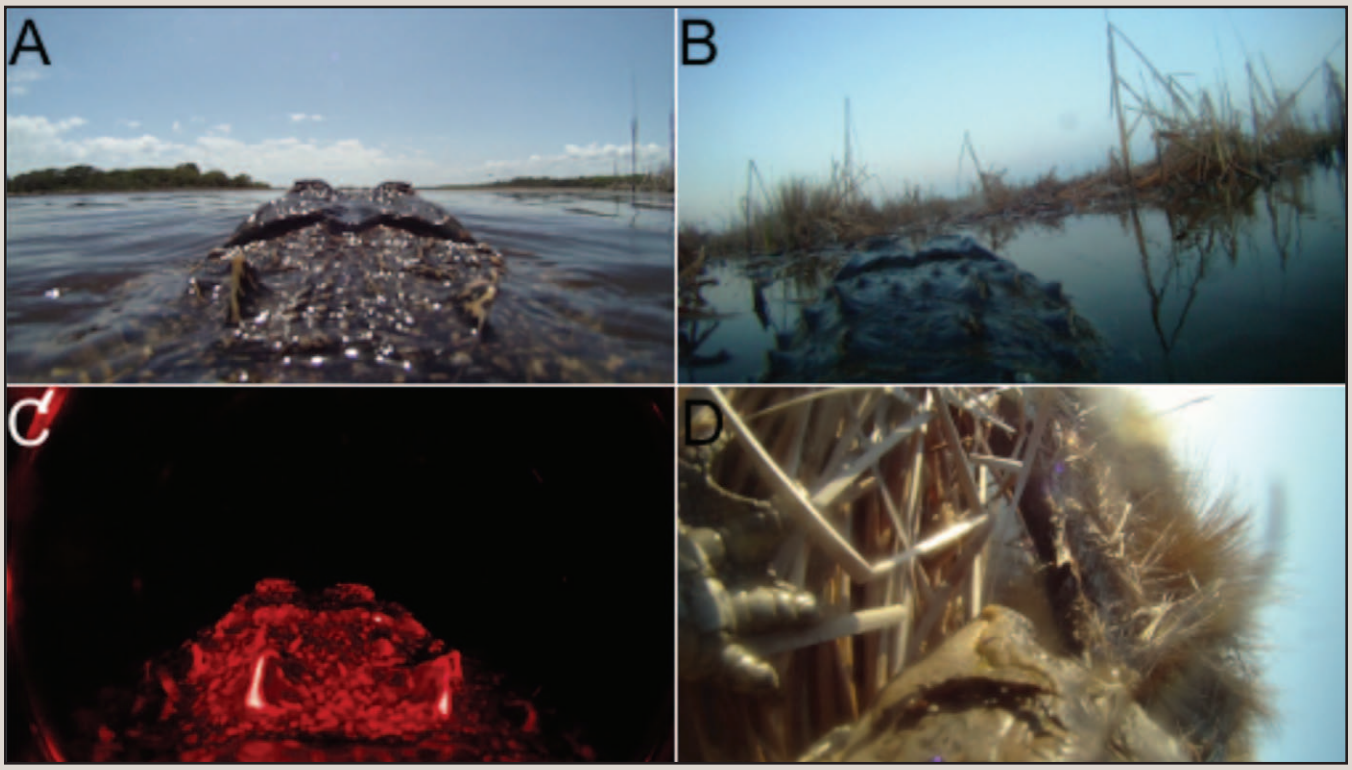

FIG. 4. Snapshots of video footage recorded during Crittercam deployments: A) Color video during day-time. B) Color video during sunrise. C) Color video during night-time. D) Side-angle view following shift in Crittercam position.

collect video and audio data from the perspective of the animal. Here, we demonstrate that animal-borne imagery devices can successfully be used to study the habits of crocodilians with little to no adverse effects on natural behavior. In comparison to direct observation, animal-borne imagery markedly increases both the quality and quantity of certain observational data which can be collected from crocodilians (Table 1). However, animal-borne imagery also has its own limitations in crocodilian studies. While the POV video produced by Crittercam offers an up-close view of animal behavior and interactions, it is restricted by the field of view and position of the camera unit. Additionally, the short duration (~8 h) of video data produced by these units may limit the amount of data available to researchers. Furthermore, when attaching equipment to wild animals there is always the potential to lose or damage the equipment.

From the outcome of deployments performed thus far, we recommend special consideration be given to the size and condition of individual crocodilians receiving Crittercams or similar types of devices. First, individuals smaller than 2 m in total length may be too small to support the added weight and drag of the Crittercam or similar data collection systems. Second, individuals in poor condition (e.g., emaciated, appearing ill or with large injuries) or physically handicapped may not be ideal candidates for camera deployments. With these limitations in mind, animal-borne imagery devices can be useful tools for recording point-of-view video and audio data of crocodilian behavior, ecological interactions, daily activity patterns, and position in the habitat. In addition, when coupled with other data collection devices such as temperature and depth sensors, this data provides an avenue to perform in-depth analyses of the effects environmental conditions have on behavioral and ecological interactions. Although we used a pre-manufactured audio/video recording device (Crittercam), we believe this method of attachment and fail-safe system could be used to deploy a variety of other devices (e.g., small cameras, depth sensors, accelerometers) on any crocodilian species at relatively little cost to researchers.

We suggest the following questions could potentially be addressed using Crittercams or similar equipment while studying crocodilians: What is the diel activity cycle (e.g., basking times, movement rates, den use, and social activities)? What are the rates of submergence? How often do crocodilians attempt to capture prey? What is the rate of success when attempting to capture prey? What foraging techniques are employed while capturing prey? Are certain foraging techniques more successful than others? How do crocodilian species differ in ecological and biological interactions?

Acknowledgments.—We thank Lou Guillette Jr., Matthew Guillette, Rachel L. Nifong, Cameron Carter, Stephanie Wies, and Carla Garreau for their assistance during this project. Additionally, we would like to thank the St. Augustine Alligator Farm Zoological Park for the use of their facilities and test subjects while refining attachment methods. This research was conducted under an award from the Estuarine Reserves Division, Office of Ocean and Coastal Resource Management, National Ocean Service, National Oceanic and Atmospheric Administration, Award No. NA10NOS4200022 (09102903). This work was also supported in part by the University of Florida Foundation (Donors: Dellecker Family), University of Florida Singer Seed Fund, and the National Science Foundation, Award No. 10021501. All animal care and use was performed in accordance with University of Florida Institutional Animal Care and Use Committee (IACUC) Protocol No. 201003798 and Kennedy Space Center IACUC Protocol No. GRD-06-044. All field collections were performed under Florida Fish and Wildlife Conservation Commission Special Permit No. SPGS-10-44R and SPGS-10-43.

A Method for Surveying Diurnal Terrestrial Reptiles with Passive Infrared Automatically Triggered Cameras

The use of automatically triggered cameras (hereafter-termed cameras) as ecological research tools has expanded considerably in recent decades (Cutler and Swann 1999; Rowcliffe and Carbone 2008). Cameras were once film-based and triggered by mechanical devices such as trip-wires, but now most systems utilize digital technology triggered by active-infrared (AIR) or passive-infrared (PIR) sensors (Swann et al. 2011). Where research questions do not require the physical capture of animals, cameras provide substantial ethical benefits over many traditional survey methods (Putman 1995) and have been shown to be superior to techniques such as live-trapping or hair-tunnels for mammals (De Bondi et al. 2010; Paull et al. 2012). Yet, while the use of cameras for understanding the distribution and ecology of mammals is well advanced, their utility for surveying other vertebrate fauna is mostly unknown. Due to trigger limitations, the use of cameras for reptile research has been restricted to a few species-specific studies. As such, this paper documents a method for use of PIR-triggered cameras to detect multiple species of diurnal terrestrial reptile.

Trigger sensitivity is a key limitation for some cameras. For reliable use, trigger mechanisms need to be sensitive enough to detect the target species, but not so sensitive that excessive false-trigger events (triggering of the camera when an animal is absent) become a hindrance (Swann et al. 2011). Guyer et al. (1997) developed a pressure-plate trigger that was successfully used to study Gopher Tortoises (*Gopherus polyphemus*) (Boglioli et al. 2003; Johnson et al. 2007), and Maier et al. (2002) developed a subterranean seismic trigger that was successfully used to study turtle nest predation (Marchand et al. 2002). However, as reptile communities include small species (< 100 g), these two types of trigger are not practical. Pressure-plates are limited by the mass of the target animal, and so a pressure-plate sensitive enough to detect small reptiles could easily become permanently depressed by displaced vegetation or substrate. Similarly, a seismic trigger sensitive enough to detect small reptiles would be prone to a high level of false-triggers as any vibration in the environment, such as weather events, would trigger the camera.

Active-infrared triggers are analogous to mechanical trip-wires; an infrared beam is transmitted to a receiver and, when broken, signals the camera to capture an image. Trigger sensitivity is generally not a problem with AIR systems but they are limited to where they can be positioned in the landscape (Rice et al. 1995). For example, animals will pass under the beam if it is placed too high, but placing it too low results in high levels of false-triggers from weather events or vegetation disrupting the beam (Rice et al. 1995; Sadighi et al. 1995; Swann et al. 2004). Consequently, AIR triggers would not be suitable for small reptiles. Still, Timber Rattlesnakes (*Crotalus horridus*), Pig-nosed Turtles (*Carettochelys insculpta*), and Gopher Tortoises have all been monitored with cameras triggered by AIR sensors (Sadighi et al. 1995; Doody and Georges 2000; Alexy et al. 2003).

Cameras triggered by PIR sensors are currently the dominant type used in ecological research (Swann et al. 2011). Passive-infrared triggers work by measuring the surface temperature, in the form of infrared radiation, emitted by objects in a detection area and trigger the camera when a rapid change in the temperature occurs; for example, when an animal with a higher or lower surface temperature than the background enters the foreground (Swann et al. 2011). Triggering based on temperature in this manner is problematic for reptiles for two reasons. Firstly, while McGrath et al. (2012) successfully detected two Grassland Earless Dragons (*Tympanocryptis pinguicolla*) with PIR triggered cameras, as reptiles can be similar in temperature to the substrate in the detection zone, they can easily avoid detection (Rovero et al. 2010). Thorbjarnarnson et al. (2000) used PIR triggered cameras to study crocodile nesting behavior and found that a crocodile managed to open the nest while only triggering the camera once.

Secondly, because surface temperatures of objects in the environment vary, temperatures within the detection zones are not uniform (Fig. 1a). Given that the camera is triggered by a thermal change in at least one zone of the detection bands, the PIR sensor requires a larger change in temperature to trigger the camera to overcome the thermal variation (Reconyx 2010). Alternatively, consider the reverse; if the temperature in the environment was homogenous, any difference in temperature becomes more pronounced and therefore more easily detected by the PIR sensor (Fig. 1b). These problems can be overcome by implementing the Camera Overhead Augmented Temperature (COAT) protocol described here. By introducing a material to augment the temperature in the detection area, in this case a cork floor tile, thermal variation is removed. Further, as the tile gets considerably

warmer than the surrounding substrate (DW, unpubl. data), reptiles will be relatively cooler, resulting in a temperature difference that triggers the camera.

Methods.—Ten Reconyx™ HC600 PIR cameras were deployed for 30 days between March 18 and April 23, 2012, to five transects (~100 m × ~2 m) on Beecroft Peninsula, Jervis Bay, Australia. The site is dominated by coastal heath; thus, each transect had previously been cleared to understory level and two camera stations established 30 m apart from a central position. Each station consisted of a Reconyx™ HC600 camera set to the highest sensitivity; a 30 × 30 cm cork floor tile; a PVC bait holder containing oats and peanut butter; two 3 m drift fences; and a camera mounting pole and block. Each station was set with the camera oriented to take overhead images from 70 cm above the ground with the cork floor tile pegged directly beneath the camera, and the bait holder pegged on the edge of the cork floor tile at the base of the mounting pole (Fig. 2). Tiles of different materials were tested prior to deployment to assess thermal absorbance. Dark-colored roof tiles would also be suitable, as they too become warmer than the surrounding substrate, but cork was selected here as it weighs less and is less fragile. White ceramic tiles were also tested; however, while cooler than the substrate the difference was not significant (DW, unpubl. data).

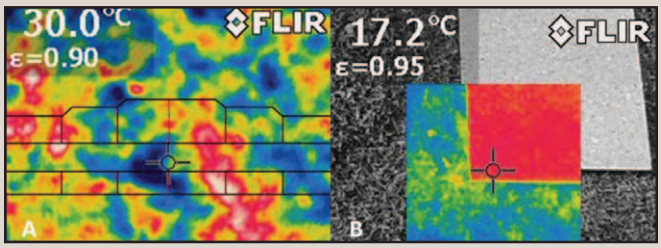

FIG. 1. Picture A) depicts the thermal variation of a 1 m² patch of grass with the Reconyx™ PIR detection bands overlaid for reference. There are six detection zones split vertically between the bands. Picture B) shows the cork tile creating a higher and uniform thermal environment.

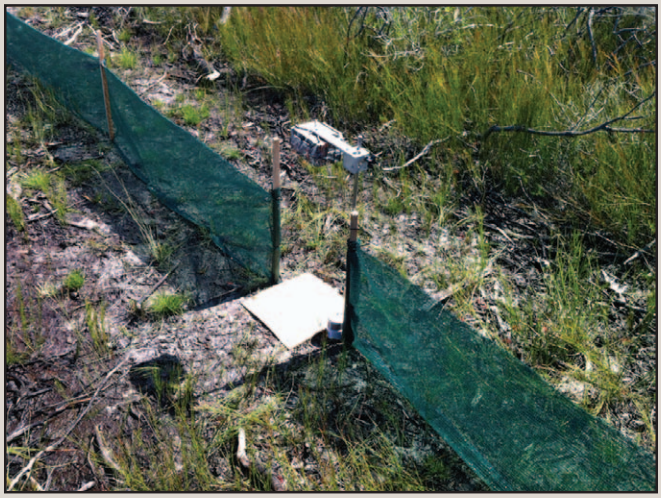

FIG. 2. The Camera Overhead Augmented Temperature protocol is set-up analogous to a pit-fall trap. Camera is oriented for detection zone bands perpendicular to the drift fence.

The PIR sensors of the Reconyx™ HC600 cameras have two parallel detection zone bands oriented left to right in the field of view (Reconyx 2010). To test whether the orientation of the detection zone was significant, each site had one camera oriented with its detection bands parallel to the direction of the drift-fence (Fig. 3b), and the other camera oriented with its detection bands perpendicular to the direction of the drift-fence (Fig. 3a). A Chi-square test was used to assess if trigger frequency varied between the detection band orientations for different groups of target species. For this analysis, species were grouped as reptiles; small mammals (< 500 g) consisting of the genera *Antechinus*, *Cercartetus*, *Mus*, and *Rattus*; and medium and large mammals (> 500 g) consisting of the genera *Macropus*, *Perameles*, and *Wallabia* (Van Dyck and Strahan 2008). One site was removed in the mammal analysis as the infrared flash of one camera failed, resulting in unidentifiable night images.

Results and Discussion.—During the deployment, 3148 trigger events occurred over the 300 trap days. Mammals accounted for ~92.3% (N = 2900) of triggers, reptiles ~3.8% (N = 118), birds ~1.8% (N = 57), and false trigger events ~2.3% (N = 73). Given the majority of trigger events occur through the night, programming the camera to be active during daylight hours or subsetting the images pre-identification can reduce the image processing time. For example, total trigger events for this deployment,

FIG. 3. Shown here is the position of the detection zone bands in Reconyx™ cameras. Picture A) has the drift fence oriented from top to bottom in the image, with detection bands oriented perpendicular to the fence. Picture B) has the drift fence oriented from left to right in the image, with detection bands oriented parallel to the fence.

between 0700 h and 1900 h, were 616. In the subsetted data, reptiles account for ~19.2% (N = 118), mammals ~63.5% (N = 391), birds ~9.3% (N = 57), and false triggers ~8.1% (N = 50).

Eight species of mammal and potentially seven species of reptile were detected (Table 1). The three smallest skink species (snout–vent length ~5 cm) on the study site were grouped together since, due to camera resolution, identification to species level was problematic (Fig. 4). This issue may be overcome by reducing the height of the camera above the ground. However, it will certainly be improved as new camera lens technology is incorporated into new models of automatically triggered camera. Despite this, this is an encouraging result for two reasons. Firstly, though future research will compare the use of this method against alternative reptile sampling methods, the COAT protocol is capable of detecting the smallest reptile species on the study area (Wilson and Swan 2010). Secondly, recent reptile surveys from 40 sites on the study area, which employed active searches and artificial refuges, have only detected 11 species of reptile after concerted effort (C. MacGregor, pers. comm., 06 Jun 2012). It is reasonable to assume therefore, that the lack of detection of other reptile species is due to the non-ubiquitous distribution of those reptiles across the site (C. MacGregor, pers. comm.).

Table 1. Reptile species detected on Beecroft Peninsula, Jervis Bay, Australia, using Reconyx™ HC600 PIR cameras.

Species Groups	Family	Scientific Name	Size (SVL mm)[A]	Detections[B]
Jacky Dragon	Agamidae	*Amphibolurus muricatus*	120	44
Mainland She-oak Skink	Scincidae	*Cyclodomorphus michaeli*	174	1
Small Skinks	Scincidae	*Lampropholis* spp.[C]	48–51	24
	Scincidae	*Saproscincus mustelinus*	55	
Eastern Blue-tongue Skink	Scincidae	*Tiliqua scincoides*	300–320	1
Red-bellied Black Snake	Elapidae	*Pseudechis porphyriacus*	1500–2000	12

[A] Snout–vent length according to Wilson and Swan 2010.
[B] Detection events occur when more than 2 minutes have elapsed since prior trigger of the same species; thus repeat triggers are considered the same event.
[C] Consists of *Lampropholis delicata* and *Lampropholis guichenoti*.

Table 2. Trigger frequency and Chi-square analysis for each target group based on orientation of the detection zone bands of Reconyx™ HC 600 PIR cameras.

Group	Parallel	Perpendicular	Chi-square (d.f. = 1)
Reptile	29	89	30.51, P < 0.0001
Small mammal	698	965	42.87, P < 0.0001
Large mammal	104	111	0.23, P = 0.69

Orientation of the detection zone bands was found to be a significant factor of trigger frequency for reptiles with the perpendicular orientation accounting for ~75% of reptile trigger events (Table 2). Orientation was also a significant factor of trigger frequency for small mammals, but did not appear to be significant for large mammals (Table 2). Orientation was initially tested because of speculation that the drift fence may bias the direction of reptile movement into the detection zone, and therefore bias detection events. Instead, the mounting-pole, bait holder, and drift fence all appeared to obscure part of the detection zone in the parallel orientation, and thereby reduced the effective detection zone. Smaller detection zones are inherently less effective at detecting animals than larger detection zones (Damm et al. 2010) and, as shown here, this effect is compounded as the size of the target species reduces. Further work regarding the efficacy of the drift fence for this method will be carried out in future studies. Despite the fact that Reconyx™ cameras were used in this study, this is still relevant if implementing this protocol with a different brand of camera due to variations in detection zone position and shape between brands (Swann et al. 2004).

Fig. 4. Small skinks can be detected, though identification can be problematic if sympatric species look similar.

Using cameras to survey reptiles provides a way to conduct capture-mark-recapture surveys without capturing the animal. Many ecological questions require animals to be identified to the individual level, and in the case of reptiles this often requires invasive marking techniques often in the form of toe-clipping, scale-clipping, or inserting subcutaneous tags (Sacchi et al. 2010). Once an animal has been captured and marked, it must then be recaptured at some point in the future, further stressing the animal and requiring additional field time for researchers. Of the 44 Jacky Dragon (*Amphibolurus muricatus*) detections, at least 15 individuals were identified from ornamental scale patterns. By eliminating the need for invasively marking individuals, ethical concerns and questions of increased mortality or diminished individual fitness are removed (Sacchi et al. 2010). Alternatively, where individual marking is required due to a lack of or changing ornamental pattern, after the initial capture and marking of individuals the COAT protocol may provide future detections without the need to recapture the individual.

One potential limitation of the COAT protocol is the need for the cork tile to reach a sufficient temperature before detections can occur. If a reptile moves into the detection zone too early (or late) in the day, the tile will not have had enough time to heat (or

will have cooled too much) and therefore reduce detection reliability. In this study however, although the mean detection time of reptiles was 1213 h (± 131 minutes), the earliest detection was at 0846 h of a small skink with the latest detection occurring at 1718 h of a Red-bellied Black Snake (*Pseudechis porphyriacus*). In a comparison of active searches and artificial refuges, Michael et al. (2012) stated "surveys were conducted on clear sunny days between 0900 hours and 1400 hours;" therefore, the times of detection recorded for this study appear no more limiting than alternative reptile survey methods.

In order to be an effective survey tool, cameras need to be capable of reliable detection of the target species while maintaining field deployability. Even though PIR triggers are limited due to the fundamental workings of the sensor, the COAT protocol shown here is a simple way to make use of PIR triggered cameras to detect reptiles. While there is still further work to do to develop this method further, this is the first successful account of employing PIR triggered cameras to deliberately target multiple species of diurnal terrestrial reptile, which others may find useful.

Acknowledgments.—I thank the Defence Support Group and University of New South Wales for financial support of this project. Field research was conducted under approval from the UNSW Animal Care and Ethics Committee (12/14A). Beecroft Weapons Range staff, Royal Australian Navy personnel, and Julia McQuoid assisted with fieldwork. Chris MacGregor provided invaluable species information of Beecroft Peninsula and Dave Paull, Andrew Claridge, and Fred Ford gave helpful editorial comments on the manuscript.

The Effect of Temperature on Weight Gain in Hatchling Mexican Kingsnakes, *Lampropeltis mexicana*

Temperature is an important component of microhabitat selection (Burger 1991) as well as influencing both behavioral and physiological changes in reptiles (Brattstrom 1965; Fitch 1968). Individuals within a species may seek various substrate temperatures based on sex, life stage, or reproductive status (Aldridge 1975; Blazquez 1995). Growth of neonates often is associated with increased energy demands (Bronikowski 2000; Bronikowski and Arnold 1999; Bronikowski and Vleck 2010; Case 1978). Consequently, neonates are thought to seek temperatures in the warmer extents of their range to facilitate more rapid growth (Dorcas 2004). However, evidence suggests both genetics and locality can both impact growth rate (Bronikowski 2000).

Thermal variation in high-elevation environments makes montane snake species an interesting group on which to conduct thermal studies. Such montane species can be found within the *Lampropeltis mexicana* complex, a popular animal in reptile husbandry where most successful breeders recommend a substantial thermal gradient (Lassiter 2012). Widely distributed, but comprised of locally isolated groups, the *Lampropeltis mexicana* complex is currently in a taxonomic state of flux with various species and subspecies designations often in contradiction with one another (Bryson et al. 2005; Bryson et al. 2007; Gartska 1982). In general, Mexicana populations are found in high-elevation environments where great fluctuations in temperature are commonplace (Bryson et al. 2007; Gartska 1982).

Given the thermal characteristics of their habitats and their prevalence in reptile husbandry, we exposed hatchling Variable Kingsnakes, *L. m. thayeri*, to two temperature regimes to investigate the impact of temperature on feeding rates, growth rates, weight gain, and efficiency of biomass accumulation.

Materials and Methods.—Each snake was placed into a container (33 L × 20 W × 12.7 cm H) containing an identical setup: a water dish, hide box containing approximately 2.5 cm of sphagnum moss (ZooMed Laboratories), and aspen cage bedding (ZooMed Laboratories) approximately 2.5–5 cm in depth. The cages had four ventilation holes drilled through each side and three on the lid. Each cage was placed into a larger cage set up (Boaphile Plastics) that contained under-cage heating tape. Temperatures were maintained within 0.6°C using two thermostats set for treatment specific temperatures (Ranco Model #ETC-111000). Data loggers (HOBO TEMP Loggers; ± 0.5°C) were used to ensure consistency within treatment groups and to quantify any variation from the programmed temperature.

Samples sizes totaled 11 hatchling snakes with 9 individuals from the same clutch and 2 from other captive clutches. Individual snakes were assigned to one of two groups (N_{group1}= 5, N_{group2}= 6) to minimize potential impacts of any differences associated with initial weights (± 0.04 g starting difference between treatments). Based upon recommended thermal gradients for the species in captivity (Lassiter 2012), we chose two treatment temperatures (23.3°C and 28.9°C). Once placed in the treatments the snakes were fed commercially obtained, frozen and thawed mice (Big Cheese Rodent Factory; 4.5 ± 3 g) twice a week, with a 3 or 4-day period between feedings. Prior to the first feeding each week, the snakes were weighed (O'Haus Adventurer balance: ± 0.002 g). Mice were left in the cages overnight and removed the next day if uneaten. Measurements were taken on the snakes from 1 Dec 2010 to 28 Mar 2011 (27 total feeding opportunities and 14 weight measurements). The process was repeated from 28 Mar 2011 to 18 Jul 2011 (27 total feeding opportunities and 15 weight measurements) with the animals switched between treatments (ex. 23.3°C is now 28.9°C, and vice versa) to minimize potential bias associated with inherent differences among individual snakes.

Throughout the experiment, cages were spot cleaned and provided with fresh water as needed. Monthly bedding changes occurred with the cleaning of all cage materials (Chlorohexidine solution).

Using repeated measures ANOVA, we evaluated the impact of both time series and temperature on weight gain. Using simple linear regression, we generated growth equations for each period and treatment and compared the slopes. Finally, we compared amount of prey refusals between treatments using a G-test while we compared the ratio of weight consumed to weight added between treatments.

Results.—Data were collected on 11 hatchling kingsnakes from 01 Dec 2010 to 18 Jul 2011, resulting in a total of 927 weight measurements taken and 14 and 15 weighings per snake per treatment (Table 1). Initial and final hatchling weights did not differ for either period (Table 2). There is an risk associated with live prey capture that would impact wild populations. Similar growth rates with the observed fewer feedings in colder temperature may better suggest optima. Growth rates for our study

BENJAMIN A. RAUSCH[1]
e-mail (BAR): s13.brausch@wittenberg.edu
RICHARD S. PHILLIPS[1]

[1]*Wittenberg University, Department of Biology, PO Box 720 Springfield, Ohio 45504, USA*

are greater than those reported by Gartska (1982) over a 2.5-year period for *L. alterna* females, suggesting a difference in growth rate over time, species differences, or different feeding regimes. Furthermore, possible costs associated with increased growth rates have been documented in many ectotherms (Gotthard 2001; Sibly and Atkinson 1994).

Our results may also have implications for husbandry. No detectable differences between temperatures suggest reptile keepers of the Mexicana kingsnakes may be able to conserve financial and logistic resources without negatively impacting growth rates of hatchlings. However, hatchling refusal of prey has been reported with this species and decreased temperature increased this propensity in our study. Furthermore, it is unknown whether the increase in efficiency of weight gain in period 2 was a consequence of the physiology of the animals or a component of increased mass of the prey items.

The sample size of our study, as well as switching snakes between temperatures, merit caution when interpreting our results. We suggest future studies maintain snakes in the same temperature for the duration of the experiment. Although the majority of our snakes were from the same clutch, our study suggests individual variation was minimal among snakes despite the presence of an outlier. We feel a study or numerous studies could be conducted on captive populations to examine the impact of faster growth rates on other aspects of individual fitness and call for increased collaborative, large-scale experiments involving both scientists and those involved in reptile husbandry.

TABLE 1. Summary weight gain data on 11 hatchling Mexican Kingsnakes during a captive study. Temperature, Initial Weight (g), Final Weight (g), Growth Rate (g/day), Ratio (grams of intake/1 g growth) for individual snakes in each time.

IN THE LARDER.

The inclusion of the Diamondback Terrapin (*Malaclemys terrapin*), or saltwater terrapin, as a New World dietary staple dates back to the arrival of European colonists in the United States in Maryland and Virginia in the late 1500s. In the United States' early years, Diamondback Terrapins were so abundant and inexpensive they were purportedly fed to pigs and, in the Chesapeake Bay region, to servants and slaves to such excess that this practice led to a slave rebellion in the 1700s. But by the 1800s, the Diamondback Terrapin became a staple in the well-to-do's larder, attaining a gourmet status in such dishes as Terrapin Maryland and Terrapin Philadelphia. The culinary status of the diamondback was brought to life in an illustrated plate prepared for the article "Canvas-Back and Terrapin," featured in an 1877 issue of *Scribner's Monthly*. The illustration in question, *In the Larder*, depicts two terrapins—one balanced atop the foot of a wine glass, the other upside-down—surrounded by the finer things in life: oysters, canvas-back ducks, a box of Flor Fina cigars, a case of Bordeaux wine from the Château Pontet-Canet. To meet this demand for terrapins, diamondbacks were collected all along the Eastern Seaboard and the Gulf Coast. Those collected from northern waters were allegedly more flavorful and considered superior to their southern cousins. "Chesapeakes" (or "Delawares") from the Delaware and Chesapeake bays commanded a higher price than did "Southerns" from North and South Carolina southward. That didn't prevent shippers and their middle-men, however, from "relocating" southern Diamondback Terrapins to more northerly latitudes, mixing them with their Chesapeake stock, and then selling the ensemble as "Chesapeakes."

Amphibian Chytrid Fungus Confirmed in Endemic Frogs and Caecilians on the Island of São Tomé, Africa

Although the presence of the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*) is confirmed on six continents, its origin is still undetermined (Kriger and Hero 2009). One of the oldest records of *Bd* in Africa is from a museum specimen collected in Cameroon in 1933 (Soto-Azat et al. 2010), and although this region is a proposed source for *Bd* (Weldon et al. 2004), the presence of the pathogen and its potential role in amphibian declines in West and Central Africa (a region that ranges from Mauritania to Democratic Republic of the Congo) are not well documented. In central Africa, the presence of *Bd* is confirmed in Gabon (Bell et al. 2011), Cameroon (Soto-Azat et al. 2010), Nigeria (Imasuen et al. 2011; Reeder et al. 2011), and Democratic Republic of the Congo (Greenbaum et al. 2008); to date there are no records of *Bd* from West Africa despite considerable sampling (Penner et al. 2013). In addition, recent surveys of Madagascar indicate that the chytrid fungus may not be present there (Vredenburg et al. 2012), raising questions about the distribution of *Bd* on oceanic islands. Collecting baseline data on the geographic and taxonomic extent of the pathogen in this region will help elucidate the extent of its distribution in Africa, and the degree of threat to local and/or endemic species.

We conducted this study on the island of São Tomé (Central Africa), a volcanic island in the Gulf of Guinea located approximately 250 km off the coast of Gabon. This island has no historic connection to the mainland and hosts five endemic amphibian species—one caecilian (*Schistometopum thomense*) and four frogs (*Hyperolius molleri, H. thomensis*, *Phrynobatrachus leveleve*, and *Ptychadena newtoni*). Two of these species—*P. newtoni* and *H. thomensis*—are listed as endangered on the IUCN Red List (www.iucnredlist.org). Because of the high level of endemism of this island amphibian community, determining whether the species are naïve to this pathogen is essential for evaluating disease risk and whether preventative measures for the island are necessary (Crottini et al. 2011).

Amphibian surveys were opportunistic and conducted at night from 9–17 April 2012 on the island of São Tomé (during the wet season). Surveyed habitats include pristine forest, disturbed forest, and agricultural fields, ranging in elevation from 65 to 1424 m (Fig. 1). We captured amphibians by hand (without gloves) and placed them in individual plastic bags until processing. We collected swab samples from 62 adults (Appendix 1) using sterile fine-tip swabs (MW113; Medical Wire & Equipment Co., Wiltshire, England). Swabs were stored in 95% ethanol and stored at 4°C until processing. All swabbed amphibians were euthanized and prepared as voucher specimens, now accessioned in the collections of the California Academy of Sciences, San Francisco, California, USA (Appendix 1).

We followed established methods for sampling *Bd* in the field, and for DNA extraction and quantitative *Bd* detection in the laboratory (Boyle et al. 2004). We analyzed 1:10 dilutions of the DNA extract in 96-well plates on a real-time PCR machine (ViiA 7; Applied Biosystems, Carlsbad, California, USA). Samples that showed signs of inhibition were further diluted to 1:100 and re-analyzed and all samples were evaluated in duplicate plates. Standard curves were generated from templates of known zoospore concentrations ranging from 0.1 to 1000 zoospores (Boyle et al. 2004). To evaluate fluorescence levels of the samples and standards we used ViiA 7 software (Applied Biosystems). Due to the overall low infection intensities in our samples, we deemed samples positive when significant sigmoidal amplification (GE ≥ 1) occurred in one or both qPCR reactions. We calculated Clopper-Pearson confidence intervals ($\alpha = 0.05$) to estimate *Bd* prevalence for *H. molleri* (the sample sizes for the remaining species were too small to produce meaningful estimates of *Bd* prevalence).

We detected *Bd* infections on four of the five species sampled (Table 1) and our survey documents the first records of *Bd* infections in these species on São Tomé. We detected *Bd* in all surveyed habitats and at all elevations, indicating that *Bd* is widely distributed on the island. The infection load for all positive individuals was low, with a maximum infection intensity of 18.3 zoospores detected on one individual of *H. molleri*. We did not observe any dead individuals or symptoms of chytridiomycosis in the field.

Our study raises questions about both the mechanisms and temporal scale of the spread of *Bd* to São Tomé and other

TABLE 1. Distribution of *Batrachochytrium dendrobatidis* (*Bd*) across species sampled on São Tomé, Africa. NI = number of infected individuals; N = total number of individuals sampled; Clopper-Pearson confidence intervals for species level prevalence ($\alpha = 0.05$); GE = genomic equivalents inferred from qPCR.

Species	NI/N	95% CI	*Bd* intensity (GE)
Phrynobatrachus leveleve	0/2	—	N/A
Hyperolius molleri	12/50	0.13–0.38	3.52 (0.67–18.26)
Hyperolius thomensis	1/3	—	9.0
Ptychadena newtoni	1/2	—	4.3
Schistometopum thomense	1/5	—	3.5

volcanic islands. Although *Bd* appears to be widespread among species throughout the island, individual infection loads ranged from 0.7 to 18.3 zoospores, which is much lower than the 10,000 zoospores known to cause severe chytridiomycosis in susceptible species (Vredenburg et al. 2010). We did not observe signs of chytridiomycosis in the field; however, our sampling is limited for four of the five species and does not address potential seasonal variation in infection intensity (Longo et al. 2010). Further studies should focus on increasing sample sizes for *H. thomensis*, *P. newtoni*, *P. leveleve*, and *S. thomense* to obtain more precise estimates of *Bd* prevalence in these species and establish baseline conditions for future monitoring efforts.

We detected *Bd* on one individual of *S. thomense*, which is one of the first records of *Bd* in a wild caecilian (Doherty-Bone et al. 2013). Though we found *Bd* in only one individual—with an estimated infection load of 3.5 zoospores—our study demonstrates that caecilians should be surveyed along with other amphibians when conducting field studies for *Bd* on São Tomé, and elsewhere. *Bd* is generally found on more aquatic anuran species (Kriger and Hero 2007), and though its presence on a more terrestrial amphibian is not unprecedented, it poses unique challenges because *Bd* infection intensities tend to vary seasonally on terrestrial species, which can make diagnosis difficult (Longo et al. 2010; Weinstein 2009). Thus, to increase the probability of detecting *Bd* in these terrestrial amphibians, surveys should include both wet and dry months (our surveys occurred during wet months).

Acknowledgments.—We thank David Rodriguez and Ana Longo for advice with qPCR; João Pedro Pio, Velma Schnoll, and Andrew Stanbridge for assistance in the field; HBD of the Bom Bom Island Resort and the Omali Lodge for logistical support and lodging. Additional logistical support was provided by EN Seligman, Roberta dos Santos, and Quintino Quade Cabral of STeP São Tomé. We thank Arlindo de Ceita Carvalho, Victor Bomfim, and Salvador Sousa Pontes of the Ministry of Environment, and the Republic of São Tomé and Principe for permission to collect and export specimens for study. Fieldwork was supported by a Cornell University Graduate Research Travel Grant (to RCB) and the California Academy of Sciences Gulf of Guinea fund. This research was conducted in compliance with the Cornell Institutional Animal Care guidelines.

Occurrence of *Batrachochytrium dendrobatidis* in *Notophthalmus viridescens* in Northwestern Virginia, USA

Batrachochytrium dendrobatidis (*Bd*) (Longcore et al. 1999), the causative agent of the amphibian disease chytridiomycosis, has caused global amphibian population declines and extinctions (Berger et al. 1998; Fisher et al. 2009; Lips et al. 2005). Little is known about the occurrence of *Bd* in northwestern Virginia, USA, and continued efforts to sample for *Bd* are needed to provide a more complete understanding of its distribution and which species are infected (Gratwicke et al. 2011). Information on the presence, prevalence, and abundance of *Bd* on host amphibian populations in this region will provide baseline data for *Bd* in local populations in order to form a basis for continued monitoring of the pathogen. In addition, if amphibians are surviving in this region despite *Bd* infection, it may suggest they possess adequate defenses, such as microbial defenses, that could be investigated to help conserve susceptible amphibians (Harris et al. 2006; Vredenburg et al. 2011).

Notophthalmus viridescens, the Red-spotted Newt, is found throughout the northeastern USA and is abundant in the George Washington National Forest (GWNF) in northwestern Virginia. Declines in newt populations have not been reported in any areas of its range, and given that this species is not cryptic and is present in ponds for several months each year, it is likely that major declines would have been detected (Hunsinger and Lannoo 2005). Therefore, this species is either not infected by *Bd* because *Bd* is not found locally, individuals are able to persist despite infection because they have adequate defensive mechanisms, such as innate immunity or microbial defenses (Harris et al. 2006; Rollins-Smith 2009) or limited surveys assessing population trends of this species have been conducted to accurately document population dynamics. Few studies have investigated *Bd* infection in *N. viridescens*, but they suggest that newts can be infected. One study in Alabama found two dead newts that were confirmed positive for *Bd*, and it was suggested that these individuals might have died as a result of chytridiomycosis (Bakkegard and Pessier 2010). In western Pennsylvania, a survey detected *Bd* infection in newts at six locations with varying prevalence (Groner and Relyea 2010), and in central Pennsylvania, infected individuals were found at 12 of 16 ponds (Raffel et al. 2010). Rothermel et al. (2008) surveyed locations throughout the southeastern USA and found newts infected with *Bd* in eastern North Carolina, northern Mississippi, and southeastern Virginia. Only two newts were sampled in Virginia, and both were positive for *Bd*, but showed no signs of disease. An additional study conducted in central Virginia sampled seven newts, all of which were negative for *Bd* (Pullen et al. 2010). Two additional studies in Virginia, one in the central Appalachians in Maryland and Virginia (Hossack et al. 2010) and one in Warren Co., Virginia (Gratwicke et al. 2011), surveyed different amphibian hosts, and found low infection prevalence across the sampled populations. Few studies have surveyed amphibian populations in Virginia and no studies to our knowledge have been completed in the GWNF in northwestern Virginia. We surveyed *Bd* infection status in *N. viridescens* populations in northwestern Virginia to determine if *Bd* was present and to assay the prevalence of infection.

Three populations of *N. viridescens* in the GWNF, including populations at Todd Lake, White Oak Flat Pond, and Mud Pond (Fig. 1), were surveyed between 27 February and 1 May 2012. Todd Lake, a medium-sized lake located at an elevation of 579 m, was surveyed on 27 Feb 2012. White Oak Flat Pond, a pond located on top of Shenandoah Mountain at an elevation of 1034 m, was surveyed on 5 March 2012 and 1 May 2012. Mud Pond, a

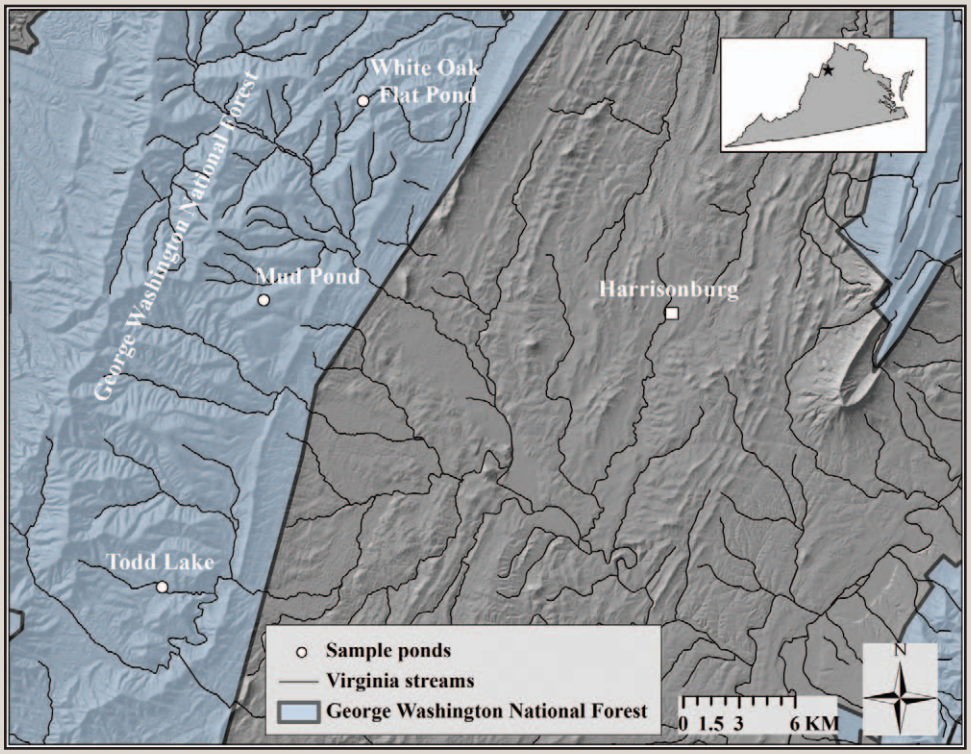

FIG. 1. Topographic map of sampling locations for *Batrachochytrium dendrobatidis* on *Notophthalmus viridescens* in the George Washington National Forest in northwestern Virginia, USA.

TABLE 1. Prevalence of *Batrachochytrium dendrobatidis* (*Bd*) infection at three sampled locations in the George Washington National Forest, Virginia, USA.

Location (date)	Number sampled (*Bd*-positive)	Prevalence
White Oak Flat Pond (5 March 2012)	10 (1)	10%
White Oak Flat Pond (1 May 2012)	39 (33)	84%
Todd Lake (27 Feb 2012)	22 (20)	90%
Mud Pond (27 March 2012)	10 (3)	30%

natural pond located at an elevation of 864 m, was surveyed on 27 March 2012. Other amphibian species, including *Lithobates sylvaticus, Pseudacris crucifer*, and *Ambystoma maculatum* were seen at the sampled locations.

During each survey, adult newts were captured using a dip net, and the presence of *Bd* was assessed using established methods that involve swabbing the skin and conducting traditional PCR (Annis et al. 2004; Hyatt et al. 2007). Unique gloves were worn for capture and swabbing of each animal to ensure that *Bd* was not transferred between individuals. Nets were not cleaned between individual captures but were cleaned in 10% bleach solution in between sample locations. Boots were also cleaned between sampling locations. Each newt was rinsed two times in 20 ml of sterile Provasoli medium (Wyngaard and Chinnappa 1982) before swabbing and then swabbed 10 times (1 swab = up and back) on the ventral body surface and one time on each foot using a Fine Tip MW 100 swab (Medical Wire and Equipment, Corsham, UK). Swabs were stored on ice until transfer to a -80°C freezer. Captured newts were visually assessed for signs of chytridiomycosis, such as lethargy, hemorrhagic lesions, reddening of the ventral region, and skin sloughing (Berger et al. 2005). Newts from Mud Pond were returned to the pond immediately following swabbing. Newts from the remaining surveys were collected for laboratory experiments (data not shown).

DNA was extracted from the swabs using Qiagen QiaAMP DNA micro kit (Qiagen, Valencia, California) following the manufacturer's protocol for DNA extraction from swabs with minor modifications. The volume of buffers ATL and AL were reduced to 200 µl. Conventional PCR was performed to detect infection. Twenty-five µl PCR reactions were completed containing the following: 2 µl of DNA extract, 2.5 µl 10X Buffer A (Fisher Scientific, Pittsburgh, Pennsylvania), 0.7 µl of 25 mM MgCl, 0.5 µl dNTPs (10 µM), 2.5 µl of each primer (10 µM), 0.2 µl Taq DNA polymerase (Fisher Scientific), and 14.1 µl of PCR-grade water. Primers *Bd*1a (5'-CAG TGT GCC ATA TGT CAC G-3') and *Bd*2a (5'-CAT GGT TCA TAT CTG TCC AG-3'), as described by Annis et al. (2004), were used. Thermocycler parameters were as follows: 94°C for 4 min, followed by 29 cycles of 94°C for 30 sec, 58°C for 1 min, and 72°C for 2 min, and a final step of 72°C for 10 min. Positive and negative controls were completed during DNA extraction and PCR. All negative controls were negative for *Bd*, and all positive controls were positive for *Bd*.

Newts were infected with *Bd*, but infection prevalence varied based on location and time of survey. In the first survey at White Oak Flat Pond, 1 of 10 sampled newts was *Bd*-positive, whereas in the second survey, 33 of 39 newts were *Bd*-positive, showing an increased infection prevalence (Fisher's Exact Test, $p = 0.037$) (Table 1). Twenty of 22 individuals sampled at Todd Lake were *Bd*-positive (Table 1). At Mud Pond, 3 of 10 sampled newts were *Bd*-positive (Table 1). The February Todd Lake sample and the May White Oak Flat Pond sample revealed variation in band intensity, suggesting variable levels of infection. It was not possible to estimate variation for the March White Oak Flat Pond and March Mud Pond samples because of the low number of positive individuals. No newts showed prominent signs of chytridiomycosis.

Bd detection in these ponds expands the known distribution of *Bd* to northwestern Virginia. Differences in *Bd* prevalence between sampling times and locations suggest that *Bd* may be responding to differences in environmental conditions, such as temperature or habitat composition, changes in transmission frequency or variation in host susceptibility. Increases in the number of amphibians entering ponds, or the frequency of contact between individuals in ponds may increase *Bd* transmission (Lips et al. 2006). For example, *Bd* prevalence increased during the time when *P. triseriata* congregated to breed in ponds in Arizona (Hyman and Collins 2012). Furthermore, newts have

an elaborate courtship ritual involving periods of sustained amplexus; therefore, the onset of courtship is an additional explanation for increased *Bd* prevalence at White Oak Flat that bears further consideration. Continued and repeated monitoring of these sites in northwest Virginia is an avenue of future research that can further investigate the possibility of temporal variation in *Bd* prevalence within these newt populations. This study, in tandem with other studies, documents *Bd* infection across the geographical range of *N. viridescens* with no signs of chytridiomycosis or striking population declines. This result suggests that newts may have a defensive mechanism, such as antimicrobial peptides or cutaneous antifungal symbionts (Harris et al. 2006; Rollins-Smith 2009). The potential defenses of newts against *Bd* warrant further investigation.

Acknowledgments.—We thank A. Loudon and J. Ramsey for assistance with fieldwork, T. Slater for permission to work in the GWNF, and Jennifer Courtwright for helpful comments on the manuscript. Collection was authorized by the Virginia Department of Game and Inland Fisheries (041297), and JMU's IACUC committee approved sampling and collection (A03-12). This research was supported by a National Science Foundation grant to RNH (1049699).

Investigations into the Life History Stages of the Common Frog (*Rana temporaria*) Affected by an Amphibian Ranavirus in the United Kingdom

Ranaviruses are emerging infectious disease agents that affect a wide range of ectothermic and poikilothermic vertebrates: fish, reptiles (including turtles and tortoises) and amphibians (Ahne et al. 1997; Chinchar et al. 2009; Miller et al. 2011). In the United Kingdom (UK), amphibian ranaviruses began to emerge in the late 1980s and early 1990s in southeast England (Cunningham et al. 1996) and manifested as adult mass morbidity and mortality events (Cunningham et al. 1993; Cunningham et al. 1996; Drury et al. 1995).

Evidence for local ranavirus outbreaks in the UK have, to date, relied exclusively upon reports of moribund or dead adult common frogs (e.g. Cunningham et al. 1993; Cunningham et al. 1996; Drury et al. 1995; Teacher 2009; Teacher et al. 2009; Teacher et al. 2010). In the majority of the cases, few frogs were collected from each site and these were usually in poor condition and thus uninformative for post mortem examinations. The sole focus on adults leaves open the question of whether earlier life history stages are susceptible to and involved in ranavirus outbreaks in the UK, as they are in North America. For example, an outbreak of the Regina Ranavirus (RRV) affected both larval and adult Tiger Salamanders (*Ambystoma tigrinum*) in Saskatchewan, Canada (Bollinger et al. 1999). Susceptibility to ranavirus infection also changes throughout development (e.g., Haislip et al. 2011; Warne et al. 2011). Therefore, it is not appropriate to assume that all life history stages are equivalent.

In Common Frogs (*Rana temporaria*), it is unknown if ranavirus infections occur naturally in eggs or tadpoles, even in locations where there is a known history of outbreaks in adults. We attempted to establish if ranavirus infections are present in the eggs and tadpoles of Common Frogs and to confirm the presence of ranavirus infections in adult Common Frogs using molecular methods.

From April to June 2007, Common Frog tadpoles were collected from 15 ponds (N = 20/pond) distributed over a 40 km^2 area around central London, UK. Eight of the ponds were known to have a history of repeated ranavirus infections in adult Common Frogs and six of the ponds were historically free of ranavirus (see Teacher 2009, Teacher et al. 2009, and Teacher et al. 2010 for pond selection). One additional site had an unknown ranavirus infection history. No die-offs were apparent in any of these ponds during our collections. All of the sites are on privately owned land, so in order to maintain confidentiality we are unable to provide more detailed location information than is provided in Tables 1 and 2.

Live tadpoles were transported in a common container in pond water to the Institute of Zoology, Zoological Society of London, London, UK. Upon arrival, tadpoles were euthanized using an overdose of MS-222 (1g/L tricaine methanesulphonate, Thompson & Joseph Ltd., Norwich, UK) buffered to pH 7.0 with sodium bicarbonate. Tissue samples were then dissected out and frozen at -80°C for ranavirus screening. In the case of larger tadpoles, tissues included the right anterior quarter of the body, and in smaller individuals, the central half was used. This sampling method ensured that commonly used tissues (e.g., liver and kidneys) for ranavirus screening were contained in the sample. Instruments were disinfected with a Virkon solution (40%; Antec International Ltd, Suffolk, UK) then rinsed thoroughly in fresh water to avoid cross contamination.

In February and March 2008, portions of four freshly laid broods of eggs were collected from each of six locations (three historically ranavirus infected sites, including Ealing and Deal, and three historically ranavirus infection free sites, including Eltham 1 and Farham 1, as per Teacher 2009, Teacher et al. 2009, and Teacher et al. 2010). A sample of ≈ 120 eggs per clutch was taken and immediately preserved in 100% ethanol. From this, a subsample of 30 eggs per clutch was taken for screening for the presence of the major capsid protein (MCP) gene of frog virus 3. Egg jelly was removed from each egg prior to DNA extraction to remove potential surface contamination as per Duffus et al (2008).

Beginning in 2006 adult frogs from suspected ranavirus mortality events were collected with the cooperation of pond owners, FrogLife (Registered Charity No. 1093372 in England and Wales), and the South Essex Wildlife Hospital. All animals received by A.L.J.D. underwent complete post mortem examinations, with hepatic tissue taken for molecular testing for the presence of the major capsid protein (MCP) of frog virus 3. The carcasses are archived at the Institute of Zoology.

DNA from eggs, tadpole tissues and adult hepatic tissue were extracted using the Wizard SV96 Genomic DNA Purification System (Promega, Southampton, UK) then screened for the presence of *Ranavirus* DNA using the polymerase chain reaction (PCR) primers and procedure of Pearman et al. (2004) and reagents from Multiplex PCR kits (QIAGEN, Crawley, UK). All samples were screened twice to ensure the repeatability and accuracy of the results. Any ambiguous results were re-screened. Positive PCR and negative extraction controls were used throughout. Originally, positive controls consisted of DNA extracts from known positive animals (Teacher 2009), but later were DNA from pure ranavirus cultures from UK frogs (Duffus 2010). The PCR products were visualized on a 1% agarose gel stained with ethidium bromide and the presence of a 500bp band was considered diagnostic for the presence of ranaviral DNA. Confidence intervals on the prevalence of infection were calculated using the calculator at http://vassarstats.net.

* Denotes that the positive result was done through isolation methods and confirmed with PCR.
† Denotes that the animals come from an unusual or mass mortality event.
CI = Confidence Interval.

Only one of the 288 tadpoles collected and screened for the presence of the MCP of FV3 was positive (Table 1). This tadpole was collected from Deal, a historically positive site where the owners intensively manage the amphibian population (i.e. actively bring in eggs and/or animals from other populations). This infection was confirmed using virus culture techniques (Duffus 2010). Unfortunately, no adult frogs were obtained from this site so we cannot ascertain whether adult frogs were concurrently or subsequently infected. No eggs screened positively for the MCP of FV3 (even those from historically positive sites such as Deal and Ealing) (N = 30 eggs/brood, 4 broods/site, 6 sites; 3 negative and 3 positive). In contrast, adult ranavirus infections were documented during all years of this study: 5 of 14 (36%) in 2006, 3 of 65 (5%) in 2007, and 24 of 41 (59%) in 2008 (Table 2). None of the frogs obtained from historically ranavirus positive sites were positive for FV3, presumably because of small sample sizes ($N \leq 4$), and hence low power to detect infections (Table 2). Animals of all three life history stages that were tested from the site in Ealing were negative for the virus, even though this site has a long history of ranavirus infection (Teacher 2009), although just a single adult animal was screened.

The extremely low prevalence of the ranavirus in Common Frog tadpoles was unexpected, as North American ranid populations seem to have persistent infections after a long history of ranavirus outbreaks (e.g., Duffus et al. 2008). Ranid tadpoles appear to be especially susceptible to infection with a variety of ranaviruses (e.g., several North American isolates; Hoverman et al. 2011; FV3 in Europe, Pearman et al. 2004; Pearman and Garner 2005). Since the susceptibility of ranid tadpoles to infection changes throughout development (e.g., Warne et al. 2011), it is possible that the sampling strategy of our study missed affected tadpoles. The tadpoles that were collected were Gosner stage 30–40 and individuals affected by the virus may have already succumbed to ranaviral disease. Future studies would benefit from sampling across developmental stages. Alternatively, there may have been very few infected tadpoles because of minimal opportunities for viral transmission from adults to tadpoles or between tadpoles. The concentration of ranavirus particles in water may not be sufficient to result in infection under natural conditions. The infection rate for some amphibian species under experimental conditions are known to be dose dependent (Brunner et al. 2005; Pearman et al. 2004).

The absence of infections in eggs is not wholly unexpected because the prevalence of ranaviral infection in ranid eggs is thought to be very low (see Duffus et al. 2008). Therefore, it is plausible that vertical or pseudovertical (where the offspring are infected by the parents but not directly through infected gametes) transmission occurs infrequently, if at all in Common Frogs.

Adult Common Frogs did test positive for infection in all years of this study. The apparent large increase in the number of infections in 2008 can be explained by an increase in sampling effort attributed to a joint campaign between the Zoological Society of London and FrogLife. The samples obtained were from frogs that had died and that pond owners themselves had submitted to the study. It is important to note that the number of ranavirus infected adults in this study does not necessarily represent the prevalence in the population where they had originated or of the true distribution of ranavirus infections in common frog populations in the UK. Although our samples of adults were small and unevenly distributed across the UK (primarily in the Southeast), it is clear that ranavirus infections are relatively common. Moreover, in many cases they were associated with unusual or large scale mortality events (e.g., Preston in the Northwest and Whitstable in the Southeast; unpubl. data).

The majority of the Common Frogs examined in this study were from historically ranavirus positive sites or from unusual mortality events that were thought to be associated with a ranavirus outbreak. However, the true extent of the distribution of ranavirus(es) in the UK needs to be determined with a structured and non-biased sampling regime that looks at multiple species and uses more sensitive molecular methods (e.g., quantitative real time PCR) to ensure that no infections are missed.

Our study is the first to address the possibility of ranavirus infections in Common Frogs affecting life history stages other than adults. While further investigations into the transmission, maintenance, and alternative hosts are required to fully understand viral dynamics, our results are consistent with the conclusion that ranavirus infections in Common Frogs in the UK predominantly affect adults. This ranavirus continues to cause mass mortality events more than 20 years since it began to emerge. A detailed understanding of the ecology and dynamics of this pathogen are essential if any conservation or management plans are to be successful.

Acknowledgments.—We thank L. Benton and J. Howard from FrogLife (Registered Charity No. 1093372 in England and Wales) and S. Schwar of the South Essex Wildlife Hospital for their cooperation in obtained adult frog samples, the multitude of people who gave A.L.J.D. free run of their gardens to collect both the egg and tadpole samples, to Shannon Duffus, Sarah Jackson-Rosario and the reviewers for their helpful comments on the manuscript. Gratitude is also extended to A. Teacher for the use of a subset of her field sites. This research was funded by an Amphibian Conservation Research Trust Student Grant, a British Herpetological Society Grant, and a Natural Science and Engineering Council (NSERC) of Canada Doctoral Scholarship to A.L.J.D., who was supported by a Queen Mary, University of London, Research Studentship, and Overseas Research Scholarship. Additional support was provided to an RCUK fellowship to T.W.J.G. All animal collection and euthanasia procedures were approved by the Ethics Committee at the Zoological Society of London.

A *Ranavirus*-related Mortality Event and the First Report of *Ranavirus* in New Jersey

Members of the genus *Ranavirus* in the family Iridoviridae have been documented on all continents with native amphibians except for Africa, though not always in amphibians (Gray et al. 2009). These viral pathogens can infect amphibians, fish, and reptiles. Infected animals typically exhibit skin lesions, organ and tissue swelling, and eventually die of organ failure (Gray et al. 2009 and references within). Ranavirus typically kills amphibians within a few days to a week of infection (Harp and Patrenka 2006), and can be transmitted via the environment, direct contact with an infected individual, or consumption of an infected individual (Pearman et al., 2004).

Although ranavirus has been detected throughout North America, including New York State (Johnson et al. 2008; Brunner et al. 2011) and the Delaware Water Gap of Pennsylvania (Glenney et al. 2010), there are currently no reports of ranavirus in New Jersey. Here we document the occurrence of ranavirus in New Jersey.

In May 2011 we were alerted to a *Lithobates clamitans* tadpole die off in Ocean County, NJ (Robert Zappalorti, pers. comm.). At the site we observed tadpoles that displayed signs consistent with ranaviral disease including lethargy, swelling, and red skin lesions. Additionally, we observed *Anaxyrus fowleri* tadpoles in the same area consuming the carcasses of dead *L. clamitans* tadpoles. Approximately one week after the initial *L. clamitans* die off, there was mass *A. fowleri* tadpole mortality. To assess whether ranavirus was the cause of this tadpole die off, we screened living and dead *L. clamitans* and *A. fowleri* tadpoles as well as other opportunistically sampled animals for the presence of *Ranavirus* DNA using Polymerase Chain Reaction (PCR) and quantitative PCR (q-PCR) at this and several nearby ponds (Table 1, Fig. 1).

Animals were sampled from five ponds located in Ocean County, New Jersey (USA), within an area that is being managed for the benefit of Pine Snake (*Pituophis melanoleucus*) populations (Fig. 1). The first site, Mitigation Pond (MP), is a retention pond immediately adjacent to a capped landfill. One side of the basin is lined and retains water year-round. The remainder of the basin is unlined, and the water level rises and falls with the water table seasonally. The second and third sites (MF Ponds) are located in close proximity to one another at the edge of a field that was artificially cleared for pine snake management (Management Field 2). Management Field 2 Breeding Pond (MF2BP2) is a small artificially constructed, unlined pond. MF2 Vernal Pool (MF2VP) is a small temporary pool covering a section of an unused unpaved road. The fourth site, Hay Pond (HP), is a large, heavily vegetated natural permanent pond. The final site, Costco Pond (CP), is a lined irrigation pond at the edge of the property near the roadside, across the road from a major shopping center. Sampling occurred on 17 May, 26 May, and 16 June 2011. Two other large permanent ponds (Beach Pond (BP) and Spotted Pond (STP)) were only sampled on 26 May.

We retrieved dead and dying *L. clamitans* tadpoles and symptomatic *A. fowleri* tadpoles by net, stored them on ice for approximately three hours, and then froze them at -20° C for 24

* Water in which the tadpole was held was screened for ranavirus, not a tissue sample.

h before DNA extraction. DNA has been shown to be present in the environment even when an organism is no longer present (Ficetola et al. 2008) so we attempted to determine if water containing asymptomatic *A. fowleri* tadpoles could test positive for *Ranavirus* DNA. We placed all apparently healthy (asymptomatic) *A. fowleri* tadpoles in 1.5 ml eppendorf tubes and allowed them to "swim" in the tube for approximately 30 seconds. Healthy tadpoles were released back to the pond and the water in the eppendorf tubes they had been in (approx. 100 ml) was frozen until DNA extraction.

We caught adult animals by net or hand and removed one toe for DNA extraction using scissors sterilized in 95% EtOH. Toes were stored at room temperature in 1.5 mL eppendorf tubes filled with Drierite desiccant to preserve DNA (Chase and Hills 1991). All adult frogs, with the exception of one dead *L. sphenocephala* (Table 1), appeared to be healthy and were released at the point of capture immediately after tissue removal. Additionally, we removed a small piece of tail tissue that included skin and muscle but no bone from a dead common Snapping Turtle (*Chelydra serpentina*) and collected a shed skin from a northern water snake (*Nerodia sipedon*) found at STP during the second sampling session.

We extracted DNA from tissue and the water that had held asymptomatic *A. fowleri* tadpoles using the Qiagen QIAamp DNA Mini Kit following the manufacturer's instructions. We digested the entire body of *A. fowleri* tadpoles and equivalent amounts of tail tissue from the *L. clamitans* tadpoles. (Since the dead tadpoles displayed varying degrees of decay, harvesting of internal organs was not possible.) Tail tissue was removed using scissors sterilized with 10% bleach. We extracted DNA from a rear leg of the *A. fowleri* metamorphs, and a toe for adult frogs. Additionally, we extracted DNA from the dead *C. serpentina* tail tissue and the shed skin from *N. sipedon* (Table 1).

We used *Ranavirus*-specific primers MCP4 and MCP5 designed by Mao et al. (1997) to amplify an approximately 530 bp fragment of the *Ranavirus* major capsid protein gene using both traditional and q-PCR. For traditional PCR we used 2 µl of DNA in 25 µl reactions that included the following components: 0.4 µM forward and reverse primers, 1.5 mM $MgCl_2$, 0.2 mM dNTPs, and 0.1 U/µl taq polymerase. We ran PCR reactions under the following conditions: 1 cycle of 95°C for 5 min followed by 30 cycles of 95°C for 30 sec, 60°C for 30 sec, and 72°C for 30 sec, followed by a final 7-min extension at 72°C. All reactions were run in a GeneAmp 9700 Thermocycler (Applied Biosystems). Appropriate negative controls using water in place of DNA were included with each PCR run. PCR products were checked for the presence of the *Ranavirus*-specific fragment on 2% 1XTAE gels by SYBR Safe (Invitrogen) staining and UV illumination. Samples were considered positive if there was a DNA fragment present at approximately 530 bp.

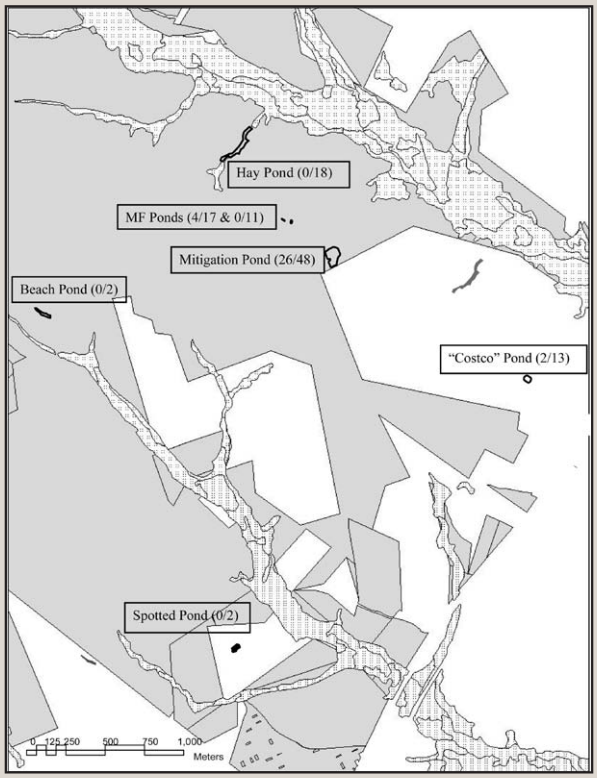

FIG. 1. Map of sampling locations in Ocean County, New Jersey. Numbers in parentheses represent number of samples testing positive for *Ranavirus* DNA / number tested.

PCR product for six putative positive samples was sequenced on an ABI 3130 Genetic Analyzer and compared to known ranavirus major capsid protein DNA sequence to confirm the presence of ranavirus DNA. All six samples were identical to each other and shared 99% similarity to an isolate of Frog Virus 3, confirming their identity as a ranavirus.

We used q-PCR to re-screen all samples. We used 4.6 µl of DNA in 10-µl q-PCR reactions that included the following components: 0.4 µM forward and reverse primers, 5 µl of Brilliant II SYBR Green q-PCR Master Mix (Agilent Technologies), and H_2O to a final volume of 10 µl. We ran positive control reactions using 2 µl of *L. clamitans* tadpole DNA that tested positive for ranavirus using traditional PCR and negative control reactions using water in place of DNA under the same conditions. PCR reactions were subjected to 1 cycle of 95°C for 10 min followed by 40 cycles of 95°C for 45 sec, 50°C for 30 sec, and 72°C for 30 sec. All q-PCR reactions were run on a StepOne Plus Real Time PCR System (Life Technologies). A sample was considered positive if the fluorescence was at least as high as the positive control.

Of the 114 animals sampled, 24 tested positive for the presence of *Ranavirus* DNA with traditional PCR and an additional eight (total of 32) tested positive with q-PCR (Table 1). The water from all 14 of the asymptomatic *A. fowleri* tadpoles from the first sampling session tested negative for ranavirus using traditional PCR, but eight tested positive with q-PCR suggesting q-PCR may be more appropriate for sampling when pathogen concentration is low. Ranaviral DNA was detected in three of the seven ponds tested, although low sample sizes prevent us from excluding its presence from the others (Fig. 1). No ranavirus was detected in the dead snapping turtle or skin shed of the water snake.

To our knowledge, this is the first published account of the presence of *Ranavirus* in the state of New Jersey. Our research demonstrates the need to sample during multiple time periods when a ranavirus outbreak is suspected of occurring. Our initial screening of *A. fowleri* tadpoles during the first sampling session, combined with their healthy physical form, gave the appearance they were not infected with *Ranavirus*. We only detected the presence of *Ranavirus* in multiple tadpoles of this species with traditional PCR after 10 days of exposure to known infected *L. clamitans* individuals in the same pond. Although we detected *Ranavirus* DNA using a non-lethal technique in asymptomatic *A. fowleri* tadpoles, further comparative tests between our non-lethal sampling (tadpole water) and tissue sampling will be necessary before we can determine if this non-lethal method is sensitive enough to consistently detect the presence of ranavirus. Future work at this site should focus on continued monitoring and screening for ranavirus over multiple seasons, and on increasing sampling effort, since for some sites where we had no positive results we did not have sufficient sample size to conclusively say those areas are actually disease free.

Acknowledgments.—We thank Robert Zappalorti and Robert Hamilton for assistance with field sampling and for Fig. 1. Animals were sampled under New Jersey Department of Environmental Protection Division of Fish and Wildlife Scientific Collecting Permit (#2011041). The study was approved by the Montclair State University Animal Care and Use Committee (permit #2011-005) and adhered to SSAR guidelines for use of amphibians in field research. Support was provided by a New Jersey Conserve Wildlife Matching Funds Grant.

Presence of *Ranavirus* in Green Frogs and Eastern Tiger Salamanders on Long Island, New York

Disease has been implicated as a factor in amphibian population die-offs and declines worldwide (Berger et al. 1998; Blaustein et al. 1994; Brunner et al. 2011; Daszak et al. 2000; Gray et al. 2009a; Green et al. 2010; Kiesecker et al. 2001; Laurance et al. 1996; Muths et al. 2006; Muths and Hero 2010; Russell et al. 2011; Skerratt et al. 2007). One hypothesis for the emergence of diseases in amphibian populations is reduced amphibian immunity associated with increased incidence of natural and anthropogenic stressors. Natural stressors include drying ponds, weather variations, and the presence of predators (Gray et al. 2009a), while the anthropogenic stressors include habitat loss and degradation, invasive species, pollution, agricultural land use, global climate change, and acid rain (Blaustein et al. 1994; Carey et al. 2003; Fellers et al. 2001; Forson and Storfer 2006; Gahl and Calhoun 2010; Gray et al. 2009a; Jaconovich et al. 2005; Kiesecker at al. 2001; Knapp and Matthews 2000 ; Pechmann et al. 1991).

While amphibians are susceptible to many pathogens, viruses belonging to the genus *Ranavirus* appear to be responsible for most amphibian die-offs in North America (Brunner et al. 2011; Collins et al. 2004; Gray et al. 2009a; Jaconovich et al. 2005; Muths et al. 2006; Phillott et al. 2010; Russell et al. 2011). The first catastrophic die-offs from *Ranavirus* in the United States were reported in the mid-1990s and have occurred in all regions of the United States (Brunner et al. 2011; Converse and Green 2005; Green et al. 2002; Jaconovich et al. 1997; Jaconovich et al. 2005; Russell et al. 2011). Furthermore, the number of reported mortality events in the United States from *Ranavirus* is 3 to 4 times greater than that for the amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (Muths et al. 2006). A variety of North American species have been affected in these mortality events, including several ranid species (*Lithobates* spp.), ambystomatid species (*Ambystoma* spp.), and plethodontid species (Bollinger et al. 1999; Brunner et al. 2011; Gray et al. 2009a; Gray et al. 2009b; Green et al. 2002; Greer et al. 2005; Jancovich et al. 1997; Jancovich et al. 2005). Undoubtedly, additional die-offs have likely occurred but have gone unnoticed.

In New York State, declines in populations of several amphibian species have been documented in recent years. The tiger salamander, *Ambystoma tigrinum*, once abundant in many wetlands throughout Long Island (Bishop 1941), is now listed as a New York State Endangered Species. Other species, such as the green frog, *Lithobates clamitans*, remain common, and their populations appear to be stable. While declines in green frog populations have not been reported, monitoring mortalities in a common species can be an indicator of potential threats to less common species. The purpose of this paper is to document observed *Ranavirus* presence in mortalities of green frogs and tiger salamanders in a single wetland population at Brookhaven National Laboratory, Long Island, New York in 2007 and 2008 (Due to the endangered status of the eastern tiger salamander in New York, we cannot report the exact locality on the BNL property).

***Present address: Brookhaven National Laboratory, P.O. Box 5000 Upton, New York 11973, USA*

In 2007, we collected 10 dead pre-metamorphic tiger salamanders at the study location. In 2008, an additional 5 dead juvenile green frogs between Gosner stages 39 and 45 (Gosner 1960) and 4 dead pre-metamorphic tiger salamanders were collected. The mortality event occurred between 6 July – 12 July in 2007, and between 24 June – 3 July in 2008, both periods being very warm and dry (above 82°F during the hottest part of the day for over a week) and occurring just prior to the animals' metamorphosis. Animals that were collected were very bloated, and their ventral surfaces were reddened. Additional carcasses were observed, but were not analyzed because of severe decomposition. We could not estimate the size of the population at this wetland, therefore we cannot provide an estimate of the percentage of the population affected.

We extracted DNA from liver tissue using the DNeasy kit (Qiagen, Valencia, CA, USA). The *Ranavirus* major capsid protein was amplified using the sense primer (5'-GACTTGGCCACTTATCAC -3') and anti-sense primer (5'-GTCTCTGGAGAAGAAGAA-3'), as previously described (Green et al. 2000; Johnson et al. 2008). Using a Taq PCR Kit (New England Biolabs), we amplified mixtures containing the extracted DNA, primers, distilled water, 10x buffer, dNTP, Mg, and Taq in a thermal cycler (PTC-100, MJ Research) with an initial denaturation at 94°C for 2 min., followed by 94°C for 20 sec., 55°C for 30 sec., and 68°C for 2 min. Then after 34 cycles of denaturation at 50°C, the mixture was annealed at 68°C for 7 min. and finally extended at 4°C. PCR products were resolved in 2.0% agarose gels, and bands were examined.

The liver samples confirmed the presence of *Ranavirus* in all nineteen collected specimens from 2007 and 2008. While we cannot conclude that *Ranavirus* caused the mortalities, it is likely that the other carcasses that were not analyzed suffered a similar fate because of the similar appearance, but more advanced decomposition, of those specimens.

The pH of the water at the time of the die-offs in both years was around 10–11, whereas the pH of Pine Barrens ponds on Long Island are generally under 6. Our pond receives storm water runoff from surrounding buildings constructed with Recycled Concrete Aggregate (RCA), which could have elevated the pH observed. It is possible that other runoff from surrounding areas (roadsides, athletic fields, buildings) might have also accumulated in this wetland. These areas are often treated for tick prevention, and salts are used in the winter on icy roads and sidewalks. While we cannot attribute the mortalities to *Ranavirus* specifically, both pesticides and road salt chemicals appear to increase susceptibility to *Ranavirus* in amphibians (Forson and Storfer 2006; Gahl and Calhoun 2010; Gray et al. 2007).

Ranavirus was previously confirmed in eastern box turtles in late 2005 at a pond 2000 m northwest of this location (Johnson et al. 2008), and box turtles were observed consuming carcasses of

larvae that were not able to transform prior to this pond drying (pers. obs.). Larval amphibians were not tested for *Ranavirus* in the nearby ponds because we were not aware of the presence of this disease prior to the observations reported here. Due to the proximity of confirmed *Ranavirus* outbreaks in box turtles, it is possible that the virus was present at our site for some time prior to these events, but was not detected.

Acknowledgments.—We thank J. Brunner and two anonymous reviewers for their comments on this manuscript. Samples were collected under Brookhaven National Laboratory IACUC #347 and New York State Department of Environmental Conservation Fish and Wildlife License #52. We thank S. Snyder, E. Efstration, and S. Miloski for assistance in the field and the laboratory.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, STANDARD ENGLISH NAME if available (for the United States and Canada as it appears in Crother [ed.] 2012. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. 7th ed. Herpetol. Circ. 39:1–92 [available from ssarbooks.com], for Mexico as it appears in Liner and Casas-Andreu 2008. *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico*. Herpetol. Circ. 38:1–162), LOCALITY (use metric for distances and give precise locality data, including lat/long coordinates in **decimal degrees** and cite the map datum used), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author; curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Sabaj Pérez [ed.]. 2010, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology: an Online Reference*, ver. 2.0, available at http://www.asih.org/) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief and must adhere to format used in this section; these should provide a geographic context for the new record). Close with author name(s) in bold, capital letters (give name and address in full—spell out state or province names—no abbreviations, e-mail address after each author name/address for those wishing to provide it—e-mail required for corresponding author). Please include distance from nearest previously known record (provide a citation or refer to existing vouchered material to substantiate your report). If publishing specific locality information for a rare or endangered species has the potential to jeopardize that population, please consult with the Section Editor at time of record submission. If field work and/or specimen collection occurred where permits were required, please include permit number(s) and authorizing agency in the text of the note.

Some further comments. The role of the "Standard Names" lists (noted above) is to standardize English names and comment on the current scientific names. Scientific names are hypotheses (or at least represent them) and as such their usage should not be dictated by a list, society, or journal.

Additionally, this geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens that have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality photograph (print, slide, or digital file) may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, the observer lacked the necessary permit for collection, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Photographic vouchers *must* be deposited in a university or museum collection along with complete locality data, and the photographic catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary), subsequent issues of *Herpetological Review*, and other sources to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. **Do not submit range extensions unless a thorough literature review has been completed.**

For reports concerning introduced species, it is important to note whether a population has become established or if the report represents an isolated occurrence, such as a released captive. Additionally, it will be helpful to include any information that establishes a timeline for the introduction, such as date of first observation.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **David C. Blackburn** (Africa and Europe), **Indraneil Das** (Asia), **Stephen Richards** (Australasia, South Pacific) **Jerry D. Johnson** (Mexico and Central America, including the Caribbean Basin), **Alan M. Richmond** (USA & Canada), or **Gustavo J. Scrocchi** (South America). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Cabral, H., and A. Caballero. 2012. Geographic distribution: Paraguay, Departamento Central: *Pseudoeryx plicatilis*. Herpetol. Rev. 43:622.

CAUDATA — SALAMANDERS

***DESMOGNATHUS AENEUS* (Seepage Salamander)**. USA: ALABAMA: Coosa Co.: First order seepage tributary of Hatchet Creek, 50 m NW of U.S. Hwy 280 (33.03820°N, 86.86.12861°W; WGS 84). 17 February 2013. S. Graham. Verified by David Laurencio. AUM 40149. New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing Co., Auburn, 347 pp.). This record fills a distribution gap for this species between Chilton County to the southwest and Clay County to the northeast.

This location is about 10 km SW of the nearest known collection site in Clay County (Mount 1975, *op. cit.*).

This specimen was collected under a special permit issued by the Alabama Department of Conservation and Natural Resources.

SEAN P. GRAHAM, Department of Biology, Pennsylvania State University, 508 Mueller Lab, University Park, Pennsylvania 16802, USA; e-mail: szg170@psu.edu.

***EURYCEA GUTTOLINEATA* (Three-lined Salamander)**. USA: GEORGIA: Cherokee Co.: Reinhardt University Campus, 0.5 km NNW of intersection of SR 140 and SR 108 (34.320915°N, 84.554160°W; WGS 84). 22 October 2010. Z. Felix. UF 169265 (Digital photograph). Verified by Kenneth Krysko.. New county record (Jensen et al. [eds], 2008. Amphibians and Reptiles of Geórgia. University of Georgia Press, Athens. 575 pp.). One adult found under cover near mucky creek

RASMER**, Department of Biology, Central Michigan University, Mt. Pleasant, Michigan 48859, USA; **KENNETH D. BOWEN**, National Park Service, Great Lakes Inventory and Monitoring Network, 2800 Lakeshore Drive East, Suite D, Ashland, Wisconsin 54806, USA.

***PLETHODON GLUTINOSIS* (Northern Slimy Salamander)**. USA: INDIANA: Sullivan Co.: Greene-Sullivan State Forest (39.00161°N, 87.25044°W; NAD 83). 25 April 2012. Sarabeth Klueh and Jason Mirtl. Verified by Chris Phillips, Illinois Natural History Survey (INHS 2012q). New county record (Minton 2001. Amphibians and Reptiles of Indiana, 2nd ed., revised. Indiana Academy of Science. vii–404 pp.).

SARABETH KLUEH and **JASON MIRTL**, Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 E. Miller Drive, Bloomington, Indiana 47401, USA (e-mail: sklueh@dnr.IN.gov).

ANURA — FROGS

***ANAXYRUS WOODHOUSII WOODHOUSII* (Rocky Mountain Toad)**. USA: CALIFORNIA: Inyo Co.: Amargosa River (35.815919°N, 116.214778°W, 360 m elev.; WGS84). 18 April 2012. Lacey Greene and Tammy Branston. Verified by S. Sweet. Natural History Museum of Los Angeles County (LACM PC 1602, 1603; photographic vouchers). New county record (Sullivan 2005. *In* M. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 438–440. Univ. California Press, Berkeley). Loud and abundant calls emanated from this section of the Amargosa River at dusk.

Historically, Rocky Mountain Toads were recorded in the Vegas Valley (Stejneger 1893. N. Amer. Fauna [7]:159–228) but more recently Rocky Mountain Toads have been observed near Las Vegas, approximately 35 km to the east (D. Bradford in Sullivan 2005, *op. cit.*). The nearest location in California is approximately 160 km to the southeast (Stebbins and McGinnis 2011. Field Guide to Amphibians and Reptiles of California, 2nd ed., revised. University of California Press, Berkeley. 538 pp.). Our record places *A. woodhousii* 130 km S and within the same river drainage as the Amargosa Toad (*A. nelsoni*). The Amargosa Toad is restricted to a ten-mile stretch of the Amargosa River in Oasis Valley, Nevada. Most of the intermittent Amargosa River channel is generally dry but water flows above ground after rainstorms (Tanko and Glancy 2001. Fact Sheet 036-01: Flooding in the Amargosa River Drainage Basin, February 23–24, 1998, Southern Nevada and Eastern California, including the Nevada Test Site).

LACEY GREENE (e-mail: lgreene@wildlife.ca.gov) and **TAMMY BRANSTON**, California Department of Fish and Wildlife, 407 West Line Street, Bishop California 93514, USA.

***DENDROPSOPHUS MIYATAI* (Hosteria La Selva Treefrog)**. COLOMBIA: CAQUETÁ: Municipio de Solano: Resguardo Indígena El Quince (0.803194°N, 75.199528°S; WGS84), ca. 204 m. elev. 6 September 2007. C. Malambo L., J. P. Nuñez, and L. Luna. Museo de Historia Natural Universidad de la Amazonia, Florencia-Caquetá, Colombia (UAM 792–796). Verified by J. D. Lynch. First department record and the westernmost for the species. Extends known range 798 km N from the previous record. Previously, this species was known only from the department of Amazonas in Colombia (Lynch 2005. Rev Acad. Colomb. Cienc. 29[113]:581–588); Ruiz-Carranza et al.1996. Rev. Acad. Colomb. Cienc. 20[77]:365–415) with the northernmost record in the Municipio de Leticia (ca. 4.116°S, 69.95°W).

CÉSAR MALAMBO L. (e-mail: malambidae@gmail.com), **MARIO A. MADRID-ORDÓÑEZ** (e-mail: mamadrido@unal.edu.co), **ALEXANDER VELÁSQUEZ-VALENCIA**, **JULIETH A. ZAPATA-ORTIZ,** and **DIANA C. ARISTIZÁBAL-VALBUENA,** Museo de Historia Natural de la Universidad de la Amazonía, Carrera 11 N° 6-69 Barrio Juan XXIII, Florencia, Caquetá, Colombia.

HYPSIBOAS CAINGUA. BRAZIL: PARANÁ: Municipality of Cianorte: 23.889626°S, 52.814711°W (SAD 69). 4 September 2012. V. G. Batista, I. P. Affonso, and F. H. Oda. Coleção Zoológica da Universidade Federal de Goiás, Goiânia, Goiás, Brazil (ZUFG 7335–7337). Verified by R. P. Bastos. The distribution of *Hypsiboas caingua* encompasses Misiones (type locality), and Corrientes provinces in northeastern Argentina (Carrizo 1990. Cuad. Herpetol. 5:32–39) and adjacent southeastern Paraguay (Brusquetti and Lavilla 2006. Cuad. Herpetol. 20:3–79) as well as isolated populations in São Paulo (Brassaloti et al. 2010. Biota Neotrop. 10[1]:275–292; Condez et al. 2009. Biota Neotrop. 9[1]:157–185; Melo et al. 2007. Biota Neotrop. 7[2]:93–102; Araujo and Almeida-Santos 2011. Biota Neotrop. 11[3]:47–62), Mato Grosso do Sul (Souza Filho and Lima 2012. Check List 8[4]:800–801; Aoki et al. 2010. Herpetol. Rev. 41[4]:507), and Rio Grande do Sul states, Brazil (Garcia and Vinciprova 1998. Herpetol. Rev. 29[2]:117–118; Kwet 2001. Frösche im Brasilianischen Araukarienwald. Anurengemeinschaft des Araukarienwaldes von Rio Grande do Sul: Diversität, Reproduktion und Ressourcenaufteilung. Münster. Natur und Tier-Verlag. 192 pp.). First state record, extends known distribution ca. 160 km NW from the closest known locality (Naviraí municipality, state of Mato Grosso do Sul; Aoki et al. 2010, *op. cit.*), and fills distributional gap.

VINICIUS GUERRA BATISTA (e-mail: vinicius.guerra_@hotmail.com), **IGOR DE PAIVA AFFONSO,** and **FABRÍCIO HIROIUKI ODA**, Programa de Pós-Graduação em Ecologia de Ambientes Aquáticos Continentais, Universidade Estadual de Maringá, Nupélia - Núcleo de Pesquisas em Limnologia, Ictiologia e Aqüicultura – Bloco G-90, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brazil.

***LITHOBATES AREOLATUS* (Crawfish Frog)**. USA: OKLAHOMA: Seminole Co.: ca. 2.3 air km NW of jct State Hwy 56 and Interstate 40; (35.40682°N, 96.46704°W; WGS84). 15 Mar 2013. Richard D. Butler. Verified by Jessa L. Watters. Sam Noble Oklahoma Museum of Natural History (OMNH 43713). New county record and a range extension of 2.8 km from Okfuskee Co. to the east (Sievert and Sievert 2011. A Field Guide to Oklahoma's Amphibians and Reptiles. Oklahoma Dept. Wildlife Conserv, 3rd ed. vi + 211 pp.). Calling males were abundant in a shallow vernal pool, air temperature was 17.2°C.

RICHARD D. BUTLER, RR 4 Box 79, Okemah, Oklahoma 74859, USA; e-mail: rdbutler@okherp.com.

***PSEUDACRIS CRUCIFER* (Spring Peeper)**. USA: INDIANA: Gibson Co.: Patoka River National Wildlife Refuge (38.362506°N, 87.379450°W; NAD 83). 22 March 2012. Sarabeth Klueh and Jason

Mirtl. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2013a photo voucher). New county record (Minton 2001. Amphibians and Reptiles of Indiana, 2nd ed., revised. Indiana Academy of Science. vii–404 pp.). Calling male captured in vegetation approx. 2 m from a semi-permanent pond.

SARABETH KLUEH and **JASON MIRTL**, Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 E. Miller Drive, Bloomington, Indiana 47401, USA (e-mail: sklueh@dnr.IN.gov).

***PSEUDOPALUDICOLA CANGA*.** BRAZIL: PARÁ: Municipality of Brasil Novo: 3.376°S, 52.576°W (datum WGS 84). 10 February 2012. E. A. Oliveira, J. C. Carvalho, and E. J. Hernández-Ruz. Museu Paraense Emilio Goeldi, Belém, Pará, Brazil (MPEG 34545–34553, MPEG 34584). Verified by M. S. Hoogmoed. Previously known only from the type locality: Serra dos Carajás, municipality of Marabá, State of Pará, Brazil (Giaretta and Kokubum 2003. Zootaxa 383:1–8). Northwesternmost record for the species, extends known distribution 260 km NW from Serra dos Carajás, the closest locality previously mentioned.

ELCIOMAR ARAUJO DE OLIVEIRA (e-mail: elcimoar.atractus@gmail.com), **EMIL JOSÉ HERNÁNDEZ-RUZ** (e-mail: emilhjh@yahoo.com), **JOYCE CELERINO DE CARVALHO** (e-mail: joyce.celerino@gmail.com), and **DAMIRES SANCHES** (e-mail: dsanx18@hotmail.com), Laboratório de Zoologia, Faculdade de Ciências Biológicas, Universidade Federal do Pará, Campus de Altamira, Rua Coronel José Porfírio, 2515 - CEP 68372040 - Altamira – PA, Brazil.

***RHACOPHORUS SUFFRY* (Suffry Red-Webbed Treefrog).** INDIA: ARUNACHAL PRADESH: Papumpare District: Nirjuli, NERIST Block-G hostel campus, 27.131547°N, 93.750133°E (WGS 84), 127 m elev. 15 August 2012. NERIST Block-P hostel campus., 27.131319°N, 93.740599°E (WGS84), 139 m asl., 20 August 2012; NERIST Block-P hostel campus, 27.131568°N, 93.749794°E (WGS 84), 140 m asl., 25 August 2012; P. C. Ray and B. Singha (ZSI/APFS/A-084). Verified by Saibal Sengupta. All three adult individuals sighted between 1900 h and 0300 h, were mostly resting on plants such as *Duranta* sp., *Begonia* sp., and *Chrysocephalum* sp. Associated anuran species include *Bufo stuarti*, *Polypedates megacephalus*, and *Duttaphrynus himalayanus*. New state record for Arunachal Pradesh, extending range ca. 125 km SE of type locality at Suffry Tea Estate, Assam, India (Bordoloi et al. 2007. Zootaxa 1653:1–20).

PARIMAL CHANDRA RAY (e-mail: parimalcray@gmail.com) and **DIANA ETHEL AMONGE** (e-mail: diana_amonge@yahoo.com), Department of Forestry, North Eastern Regional Institute of Science and Technology, Itanagar 791 109, Arunachal Pradesh, India; **MOUSUMI RAJBONGSHI,** Animal Ecology and Wildlife Biology Lab., Department of Zoology, Gauhati University, Guwahati 781 014, Assam, India (e-mail: rajmousumi19@gmail.com).

***THELODERMA HORRIDUM* (Thorny Bush Frog).** MALAYSIA: SARAWAK: Miri (Fourth) Division: Lambir Hills National Park, vicinity of Borneo Tropical Rainforest Resort (04.176551°N, 113.993948°E; WGS84). 16 February 2013. Photographic voucher, Raffles Museum of Biodiversity Research, National University of Singapore, ZRC [IMG] 1.42a–c. C. Lee. Inoue Trail, near Park Headquarters (ca. 4.300000°N, 113.66667°E). 24 September 2012. Photographic voucher, ZRC [IMG] 1.43a–b. Y. Emang and H. R. Kiprawi. Verified by Kelvin K. P. Lim. In both cases, found on trunks of live trees. Specimen on 16 February encountered ca. 2100 h, ca. 2 m on tree trunk. No vocalization heard. First locality record for Sarawak State, and second for Borneo, only known population on Borneo reported from Danum Valley (5.016667°N, 118.05°E), Lahad Datu District, Sabah (Inger et al. 1995. Raffles Bull. Zool. 43:115–131), ca. 492 km to the northeast (linear distance calculated using Movable Type Scripts, http://www.movable-type.co.uk/scripts/latlong.html). Known distribution outside Borneo includes southern Peninsular Thailand, Peninsular Malaysia, Pulau Tioman, Singapore, and the Mentawai Archipelago (Dring 1979. Bull. Brit. Mus. Nat. Hist. Zool. 34:181–241; Figueroa and Selveindran 2011. Nat. Singapore 4:259–262).

TESTUDINES — TURTLES

***CHRYSEMYS PICTA MARGINATA* (Midland Painted Turtle)** USA: MICHIGAN: Charlevoix Co.: Southwest end of Hog Island, Eastern Lake Michigan (Beaver) Archipelago (45.775096°N, 85.394518°W; WGS 84). 12 July 2011. Nancy E. Seefelt. Verified by Fred Janzen. Iowa State University Research Collection (ISUA201202; digital images). New record for Hog Island (Bowen and Gillingham 2004. Michigan Acad. 35:213–223). Turtle shell was found in a coastal wetland on the island; other turtles were observed in the area.

NANCY E. SEEFELT (e-mail seefe1ne@cmich.edu), **JAMES C. GILLINGHAM**, **PATRICK D. FARRELL**, **LORRIN A. ORTMANN,** and **DESIREE R. RASMER**, Department of Biology, Central Michigan University, Mt. Pleasant, Michigan 48859, USA; **KENNETH D. BOWEN**, National Park Service, Great Lakes Inventory and Monitoring Network, 2800 Lakeshore Drive East, Suite D, Ashland, Wisconsin 54806, USA.

***PELODISCUS SINENSIS* (Chinese Softshell Turtle)**. BRAZIL: BELÉM: Belém City (1.366°S, 48.392°W; datum WGS 84). February 2010. D. Félix-Silva, J. Pezzuti. MPEG 1214. Verified by Marinus Hoogmoed. Pelodiscus sinensis is a South Asian species that has been introduced in several localities outside its natural range, and was recently reported in Amazonia (Félix-Silva et al. 2012 Herpetol. Rev. 43:616). Due to heavy exploitation for food and traditional medicine, natural populations are seriously depleted and *P. sinensis* is now considered vulnerable in its native range (Asian Turtle Trade Working Group 2000. *In* IUCN 2012. IUCN Red List of Threatened Species. Version 2012.2. <www.iucnredlist.org>. Accessed 3 November 2012). Here we report additional Brazilian specimens.

The specimens reported here were found and captured in small bodies of water near densely inhabited neighborhoods in Belém City, Brazil (1.366°S, 48.392°W; datum WGS 84). Two hatchlings (about 20 mm carapace length) were found by children in a sandy place next to an artificial lake in February 2010 (MPEG 1214). One year later, three similarly-sized young animals were caught at the same locality. An adult male was caught in a hole near the same lake in November 2010 (MPEG 1215). In April 2011 an adult female was found nearly 1 km downstream from the first locality (MPEG 1216). This individual laid five small spherical eggs in the water 9 May 2011 and three more eggs on 31 May 2011. After 60 days of incubation, none of the eggs showed any sign of embryonic development. It seems probable that there is a feral population of unknown size established in the streams and lakes of Belém City, and studies on the distribution and impacts of *P. sinensis* on local aquatic habitats and aquatic biodiversity are recommended.

DANIELY FÉLIX-SILVA, Núcleo de Altos Estudos Amazônicos, Universidade Federal do Pará/UFPA, Belém, Pará, Brazil (e-mail: danyfelix30@gmail.com); **EMIL JOSÉ HERNÁNDEZ-RUZ**, Laboratório de Zoologia, Faculdade de Ciências Biológicas, Universidade Federal do Pará/UFPA, Campus de Altamira, Rua Coronel José Porfírio, 2515 - CEP 68372040 - Altamira – PA, Brazil; **MANOELA WARISS FIGUEIREDO** and **JUAREZ CARLOS BRITO PEZZUTI**, Núcleo de Altos Estudos Amazônicos, Universidade Federal do Pará/UFPA, Belém, Pará, Brazil.

***PSEUDEMYS CONCINNA* (River Cooter)**. USA: GEORGIA: Cherokee Co.: Ball Ground, intersection of state highways 369 and 372 (34.277379°N, 84.298898°W; WGS 84). 9 July 2011. Z. Felix. UF 166972 (Digital photograph). Verified by Kenneth Krysko. One adult female found alive on road mid-afternoon. New county record (Jensen et al. [eds;] 2008. Amphibians and Reptiles of Geórgia. University of Georgia Press, Athens. 575 pp.).

ZACH I. FELIX, Biology Department, Reinhardt University, Waleska, Geórgia 30183, USA; e-mail: zif@reinhardt.edu.

***TRACHEMYS SCRIPTA* (Pond Slider)**. USA: NEVADA: Washoe Co.: Reno, Rancho San Rafael Regional Park, Peavine Pond (39.54606°N, 119.83107°W; NAD83). 3 June 2006. Photographed by Fredric F. Petersen. Verified by Jens Vindum. CAS-HPV 74 photo voucher. First record for Nevada. *Trachemys scripta* has been introduced widely in the western USA through the pet trade (Rhodin et al. 2010. Chelon. Res. Monogr. No. 5: 000.85-000.164). The species is known from many sites in the Central Valley of California (Thomson et al. 2010 Chelon. Conserv. Biol. 9:297–302, and references therein), with the closest previous record (Thomson et al., *op. cit.*) being approximately 166 km WSW of this first Nevada record.

Pond Sliders appear to be common in urban ponds and lakes in Reno and Sparks, Nevada (additional localities are documented by CAS-HPV 72, 73, and 75. An individual photographed on 19 June 2011 (CAS-HPV 72) with mud covering the hind limbs, tail, and rear edge of the carapace, suggesting it had been digging a nest provides circumstantial evidence of breeding in the area. Reports of this species (without vouchers) also exist for Clark County in southern Nevada (FFP, pers. obs.).

FREDRIC F. PETERSEN, 2080 King Edward Drive, Reno, Nevada 89503, USA (e-mail: Fugle@aol.com); **ALAN DE QUEIROZ,** 826 Delmar Way, Reno, Nevada 89509, USA (e-mail: alandqz@yahoo.com); **CHRIS R. MENDELSON III**, Zoo Atlanta, 800 Cherokee Avenue Southeast, Atlanta, Georgia 30315, USA (e-mail: jmendelson@zooatlanta.org); **ROWAN J. FELDMAN-MATOCQ**, 2900 Sagittarius Drive, Reno, Nevado 89509, USA.

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider)**. USA: INDIANA: Lawrence Co.: approx. 7 mi SW of Bedford on Hwy 50 (38.77892°N, 86.55451°W; NAD 83). 14 March 2012. Sarabeth Klueh and Jason Mirtl. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2012r). This capture provides a new county record for Indiana (Minton 2001. Amphibians and Reptiles of Indiana, 2nd ed., revised. Indiana Academy of Science. vii–404 pp.).

SARABETH KLUEH and **JASON MIRTL**, Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 E. Miller Drive, Bloomington, Indiana 47401, USA (e-mail: sklueh@dnr.IN.gov).

SQUAMATA — LIZARDS

***ACANTHODACTYLUS MICROPHOLIS* (Persian Fringe-toed Lizard)**. IRAN: BUSHEHR PROVINCE: 20 km SE of Khoormouj, near Naseri village (28.489644°N, 51.473191°E), 10 m elev. Kamran Kamali, Behzad Zadhoosh, and Shahrzad Malekzadeh. 22 February 2013. Iranian Herpetological Institute (IHI0014: one adult female; IHI0015: one adult male). Verified by Steven C. Anderson. This is the first record of this species from Bushehr Province. Individuals were found among low hills on sandy riverbeds with scattered bushes and in narrow canyons on stream beds covered with small bushes and grass. The specimens fit the diagnosis and color pattern in Anderson (1999. The Lizards of Iran. SSAR Contrib. Herpetol., Ithaca, New York. 442 pp.). The nearest reported locality is 480 km E of the record noted here (27.016667°N, 55.716667°E), 109 km W

of Bandar-e-Abbas to Kerman road along road to Bandare-e-Lengeh, 0–50 m elev (MMTT [Muze-ye Melli-ye Tarikh-e Tabii, Tehran] 813; Anderson 1999:205–206). This is the first record from Bushehr Province and for the southwestern part of Iran. **KAMRAN KAMALI**, Iranian Herpetological Institute, Apt. #2, No. 19, 7th alley, Nima youshij St., Shahran Blvd., Tehran, Iran, 14788-54818; e-mail: canis58@yahoo.com.

***ALEXANDRESAURUS CAMACAN* (Alexandre's Lizard, Calanguinho do Alexandre)**. BRAZIL: BAHIA: Municipality of Amargosa: Timbó Farm (13.11058°S, 39.6673°W; WGS 84), 800 m elev.; Municipality of Jaguaripe: 13.19238°S, 39.00191°W. 21 November 2011. M. Matos. Museu de Zoologia, Universidade Federal da Bahia (UFBA 3019, 3033, 3034; adults collected in pitfall in pristine tropical forests). Verified by M. Rodrigues. Previously known from five localities in Bahia (Freitas et al. 2007. Herpetol. Rev. 38:481; Rodrigues et al. 2007. Amer. Mus. Novit. 3565:1–27). The new records fill a distributional gap in the range of the species. The Amargosa record extends the distribution 190 km SW from Municipality of São Sebastião do Passé and 177 km NW from Uruçuca, and represents the interiormost record known.

MARLLA ALVES MATOS (e-mail: marllamatos17@hotmail.com) and **MILENA CAMARDELLI**, Department of Biology, Universidade Federal da Bahia, Salvador, Bahia, CEP 40170-290, Brazil; **EUVALDO MARCIANO-JR.**, Programa de Pós-Graduação em Ecologia e Conservação da Biodiversidade, Universidade Estadual de Santa Cruz, Ilhéus, Bahia, 45662-900, Brazil.

***ASPIDOSCELIS SEXLINEATA* (Six-lined Racerunner)**. USA: GEORGIA: Cherokee Co.: Ball Ground, 1.30 km SE of intersection of Lower Dowda Mill Rd. and Soap Creek Rd. (34.365784°N, 84.427675°W; WGS 84). 24 June 2012. Z. Felix. UF 169262. Digital photograph. Verified by Kenneth Krysko. One adult gravid female captured in funnel trap in middle of field. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Geórgia. University of Georgia Press, Athens. 575 pp.).

ZACH I. FELIX, Biology Department, Reinhardt University, Waleska, Geórgia 30183, USA; e-mail: zif@reinhardt.edu.

***CROTAPHYTUS BICINCTORES* (Great Basin Collared Lizard)**. USA: NEVADA: Washoe Co.: Hays Canyon Range (41.415183°N, 119.978771°W; WGS84; elev. 1392 m). 7 July 2012. Verified by Jimmy A. McGuire. MVZ 20444–20457 (photo vouchers). First record from this mountain range (McGuire 1996. Bull. Carnegie Mus. Nat. Hist. 32:1–143; St. John 2002. Reptiles of the Northwest. Lone Pine Publ., Renton, Washington. 272 pp.; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. 3rd ed. Houghton Mifflin Co., Boston, Massachusetts. 533 pp.). Specimen was an adult male. An adult female (MVZ 35933–35935 photo vouchers) was also recorded.

In Nevada this extends the distribution for this species in Washoe Co. ca. 89 km N from "Smoke Creek, 0.25 and 1 mi from Nevada state line" (MVZ 20444–20457) and 68 km W from Soldier Meadow, Humboldt Co. (MVZ 35933–35935). In Oregon the nearest reported locality is from the Pueblo Mountains, Harney Co. at "14 mi N Denio" (OSUMNH 8817–8823), ca. 140 km to the NE.

Both specimens were observed basking on boulders along Co. Rd 37 in Surprise Valley at base of W slope of the Hays Canyon Range, 1.75 km E of California border.

We thank Steve Arnold for providing catalogue data for vouchers of this species in the OSUMNH collection.

***HEMIDACTYLUS MABOUIA* (Wood Slave)**. USA: FLORIDA: Brevard Co.: Eddy Creek (28.67568°N, 80.64768°W;WGS 84). 7 June 2012. Nathan Byer, Kaite Anderson, and Richard Seigel. Verified by Walter Meshaka, Jr. Fort Hays State University's Sternberg Museum of Natural History (FHSM 16500 photo voucher). First reported record from Canaveral National Seashore and a range extension of 24.22 km NE of neartest reported location: I-95 between SR 406 and 405 in Titusville (Criscione et al. 1998. Herpetol. Rev. 29[4]:248.

Found inside of storage shed at Eddy Creek Parking Area, Playalinda Beach, Canaveral National Seashore. In January 2013, two additional lizards were seen at this locality. One specimen was photographed, captured, preserved, and stored with the National Park Service.

NATHAN BYER (e-mail: nbyer1@students.towson.edu), **KAITE ANDERSON**, and **RICHARD SEIGEL**, Department of Biological Sciences, Towson University, Towson, Maryland 21286, USA.

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko)**. USA: TEXAS: Chambers Co.: Anahuac National Wildlife Refuge (29.61377°N, 94.53398°W, WGS 84; elev. 2 m), on an exterior bathroom wall near the entrance to the refuge. 27 July 2012. William L. and Limei T. Farr. Verified by Carl J. Franklin. UTADC 7639. First county record (Dixon 2013. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station. 447 pp.). This record fills a gap in county records from east Texas for this invasive species. *Hemidactylus turcicus* was also observed in abundance (ca. 10–20 individuals on each date) and photographed in situ at this same locality, and on other small adjacent buildings including the visitor's center and a kiosk on the evenings of 13 July 2012, 24 Aug 2012, and 28 Sept 2012. This appears to be a well-established population.

WILLIAM L. FARR, 11019 Wainfleet Lane, Houston, Texas 77096, USA; e-mail: williamfarr@sbcglobal.net.

LEPOSOMA PUK. BRAZIL: BAHIA: Municipality of Amargosa: Timbó Farm (13.11058°S, 39.6673°W; datum WGS 84), 800 m elev.

21 November 2011. M. Matos. Verified by M. Rodrigues. Museu de Zoologia, Universidade Federal da Bahia, Salvador, Bahia, Brazil (UFBA 3018 adult, collected in a pitfall in a pristine tropical forest). Previously known from three localities in southern Bahia State, Brazil: municipalities of Jussari, São Jose da Vitória, and Una (Rodrigues et al. 2002. Pap. Avulsos Zool. 42[14]:335–350). The new record extends the known distribution about 180 km N of the nearest previous record (Municipality of São José da Vitória; Rodrigues et al., *op. cit.*).

MILENA CAMARDELLI (e-mail: milenacamardelli@yahoo.com.br) and **MARLLA ALVES MATOS**, Department of Biology, Universidade Federal da Bahia, Salvador, Bahia, CEP 40170-290, Brazil; **EUVALDO MARCIANO-JR.,** Programa de Pós-Graduação em Ecologia e Conservação da Biodiversidade, Universidade Estadual de Santa Cruz, Ilhéus, Bahia, 45662-900, Brazil.

***MESALINA BREVIROSTRIS* (Blanford's Short-nosed Desert Lizard)**. IRAN: HORMOZGAN PROVINCE: 5 km NW of Parsian, near Milaki village (27.234114°N, 52.990888°E), 18 m elev. Kamran Kamali, Behzad Zadhoosh, and Shahrzad Malekzadeh. 25 February 2013. Iranian Herpetological Institute (IHI0022: adult female). Verified by Omid Mozaffari. This species has been recorded from Khoozestan, Bushehr Provinces and Tonb-e-Bozorg and Qeshm Islands in Persian Gulf (Rastegar-Pouyani et al. 2008. Field Guide to Reptiles of Iran, Volume 1: Lizards. Razi University Press). This is the first record of this species from mainland Hormozgan Province. Individual was found on a plain with alkaline soil covered with scattered small bushes and shrubs. The specimen fits the diagnosis and the color pattern in Anderson (1999. The Lizards of Iran. SSAR Contrib. Herpetol., Ithaca, New York. 442 pp.). The nearest reported localities are Tonb-e-bozorg Island (WB [William T. Blanford] 74, 76) and Qesm Island (CAS 96153) (Anderson 1999:249–251), 250 and 300 km SE of the reported locality, respectively. Another nearby locality is Ahram in Bushehr Province (FMNH 141492; Anderson 1999:249–251), 250 km NW of the locality reported here.

KAMRAN KAMALI, Iranian Herpetological Institute, Apt. #2, No. 19, 7th alley, Nima youshij St., Shahran Blvd., Tehran, Iran, 14788-54818; e-mail: canis58@yahoo.com.

***STENODACTYLUS AFFINIS* (Iranian Short-fingered Gecko)**. IRAN: HORMOZGAN PROVINCE: 5 km NW of Parsian, near Milaki village (27.234114°N, 52.990888°E), 18 m elev. Kamran Kamali, Behzad Zadhoosh, and Shahrzad Malekzadeh. 25 February 2013. Iranian Herpetological Institute (IHI0023: adult male). Verified by Omid Mozaffari. This is the first record of this species from Hormozgan Province. It was found on a plain with alkaline soil covered with scattered small bushes and shrubs. The specimen fits the diagnosis and the color pattern in Anderson (1999. The Lizards of Iran. SSAR Contrib. Herpetol., Ithaca, New York. 442 pp.). The nearest reported locality is 2–3 km SSE Bushehr (KS [Karl P. Schmidt] 55) 300 km from the reported locality Anderson (1999:182–183).

KAMRAN KAMALI, Iranian Herpetological Institute, Apt. #2, No. 19, 7th alley, Nima youshij St., Shahran Blvd., Tehran, Iran, 14788-54818; e-mail: canis58@yahoo.com.

***TROPIOCOLOTES LATIFI* (Latifi's Dwarf Gecko)**. IRAN: QOM PROVINCE: 2 km S of city of Qom (34.571972°N, 50.870742°E), 1069 m elev. 17 November 2012. Seyyed Mehdi Mirghazanfari. Iranian Herpetological Studies Institute (IHSI0011: adult male; IHSI0012: juvenile). Verified by Kamran Kamali. First record for Qom Province. A suitable habitat for this species was found and one adult male and one juvenile were collected at 1600 h on a plain covered with gravel and small to medium-sized rocks near a mountain with scattered bushes. The specimens were inactive beneath a rock. The nearest reported locality is center of Isfahan Province, 27 km S of Kashan (Zoological Museum of Razi University; GT.20.2, GT.20.3), 130 km from the locality reported here (Rastegar-Pouyani et al. 2009. Zoology in the Middle East 47:105–1070.

***HETERODON PLATIRHINOS* (Eastern Hognose Snake).** USA: GEORGIA: Cherokee Co.: Ball Ground, north of Creighton Rd., 0.45 km E of intersection with SR 372 (34.294587°N, 84.307530°W; WGS 84). 10 October 2012. Z. Felix. UF 169263. Digital photograph. Verified by Kenneth Krysko. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Geórgia. University of Georgia Press, Athens. 575 pp.). One juvenile captured in wooded lawn.

ZACH I. FELIX, Biology Department, Reinhardt University, Waleska, Geórgia 30183, USA; e-mail: zif@reinhardt.edu.

***LAMPROPELTIS CALLIGASTER* (Yellow-bellied Kingsnake).** USA: TEXAS: Caldwell Co.: TX Hwy 80, 0.97 rd. km N jct. TX Hwy 130 (29.79221°N, 97.79167°W; WGS 84). 19 June 2012. Drew R. Davis. Verified by Travis J. LaDuc. Texas Natural History Collections, TNHC 85239. New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station. 421 pp.). A second individual (TNHC 85240) was also found the same night. Specimens were collected under a Texas Parks and Wildlife Scientific Collecting Permit (SPR-0511-126) to Drew R. Davis.

DREW R. DAVIS, Texas State University, Department of Biology, 601 University Drive, San Marcos, Texas 78666, USA; e-mail: drewdavis@txstate.edu.

***LAMPROPELTIS ZONATA* (California Mountain Kingsnake)** USA: CALIFORNIA: San Benito Co.: San Juan Bautista, 2.11 km ENE Fremont Peak on San Juan Canyon Road at intersection with undesignated road (36.7655°N, 121.4827°W; WGS 84), elev. 825 m. 6 June 2009 at 1450 h. Snake found DOR. Nick Dana Waters. Verified by Carol Spencer. MVZ 269317. This is the first report within San Benito Co. and the Gabilan Range. Nearest localities are within the Santa Lucia Range 46 km SW near Carmel-By-The-Sea, Monterey Co. (MVZ 97822), and within the Santa Cruz Mountains 45 km NW at Uvas Canyon, Santa Clara Co. (CAS 190482). This specimen most closely resembles the Santa Clara color morph (Mitch Mulks, pers. comm.). Dominant structural flora include *Quercus chrysolepis, Q. agrifolia, Pinus sabiniana,* and *Arctostaphylos* sp. in adjacent chaparral.

NICK D. WATERS, 5229 West Spur Drive, Phoenix, Arizona 85083-1285, USA; e-mail: nickdwaters@gmail.com.

***LICHANURA TRIVIRGATA TRIVIRGATA* (Mexican Rosy Boa).** USA: ARIZONA: Pima Co.: West Silver Bell Mountains (32.438219°N, 111.573397°W; WGS 84), elev. 686 m. 01 May 2010. Paul Lynum and Jason Pike. University of Arizona (UAZ PSV 57458). Verified by A. T. Holycross. The nearest vouchered localities are from ca. 75 km to the WNW in the Sand Tank Mountains and ca. 90 km to the NW in the North Maricopa Mountains (Holycross and Brennan 2006. A Field Guide to Amphibians and Reptiles in Arizona. Arizona Game and Fish Department, Phoenix. 150 pp.). Subadult female collected at 1610 h in a dry wash surrounded by Sonoran Desertscrub (Arizona Upland Subdivision).

Two additional specimens (UAZ PSV 57459 and 57460) were photographed in the same location on 21 March 2012.

PAUL LYNUM, 2820 North Mohawk Trail, Chino Valley, Arizona 86323, USA (e-mail: paullynum@earthlink.net); **JASON PIKE**, 641 Juanita Street, La Habra, California 90631, USA.

***OPHEODRYS AESTIVUS* (Rough Green Snake).** USA: TENNESSEE: Weakley Co.: Found dead on shoulder of TN Hwy. 43 approximately 30 m S of intersection with University Street in Martin, Tennessee (36.3472°N, 88.8731°W; WGS 84). 05 May 2012. Tom Blanchard. Verified by A. Floyd Scott. Austin Peay State University (APSUMZ 19252). New county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/reptatlas/, latest update 04 December 2012, accessed 18 January 2013).

***STORERIA DEKAYII* (Dekay's Brownsnake)** USA: MICHIGAN: Charlevoix Co.: Southwest end of Hog Island (Grape Spit), Eastern Lake Michigan (Beaver) Archipelago (45.777581°N, 85.407715°W;

WGS 84). 12 July 2011. Nancy E. Seefelt. Verified by Fred Janzen. Iowa State University Research Collection (ISUA202203; digital images). New record for Hog Island and the Beaver Archipelago (Bowen and Gillingham 2004. Michigan Acad. 35:213–223). Snake was found under a deflated rubber trampoline with other snakes, including Northern Water Snakes (*Nerodia sipedon*) and Eastern Garter Snakes (*Thamnophis sirtalis*). The voucher, a gravid female, was photographed and released at the site.

NANCY E. SEEFELT (e-mail seefe1ne@cmich.edu), **JAMES C. GILLINGHAM**, **PATRICK D. FARRELL**, **LORRIN A. ORTMANN,** and **DESIREE R. RASMER**, Department of Biology, Central Michigan University, Mt. Pleasant, Michigan 48859, USA; **KENNETH D. BOWEN**, National Park Service, Great Lakes Inventory and Monitoring Network, 2800 Lakeshore Drive East, Suite D, Ashland, Wisconsin 54806, USA.

***THAMNOPHIS BUTLERI* (Butler's Gartersnake)**. USA: WISCONSIN: Jefferson Co.: Town of Whitewater (42.84699°N, 088.74271°W; WGS 84). 13 June 2012. Joshua M. Kapfer and Kerry Katovich. Verified by Erik Wild (University of Wisconsin-Stevens Point). University of Wisconsin-Stevens Point Collections (UWSP 0162–0165 photo vouchers; tissue sample catalogued UWSP 4534). New county record (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin. Milwaukee Public Museum, 87 pp.). Extends the currently known range of this species in Wisconsin.

The identification of these specimens as *T. butleri* was supported by genetic analyses with techniques previously developed by Sloss (2011. Genetic identity of Wisconsin gartersnakes [*Thamnophis* spp.] using microsatellite genetic markers. Wisconsin Department of Natural Resources Research Report 192: PUB-SS-592-2011; http://dnr.wi.gov/topic/EndangeredResources/documents/SlossReport.pdf; accessed 15 February 2013). The accessioned tissue sample represents an individual whose genetic profile was consistent with a pure Butler's Gartersnake (BGS) (mean STRUCTURE q-value of 0.8018% with a threshold of 80% for identifying pure BGS per Sloss 2011; BLS, unpubl. data).

Several adult individuals were captured under artificial cover objects (photographed with tissue samples collected) on 13 June 2012. Juveniles were also captured in the same manner during September 2012 surveys, indicating a reproductive population. Associated habitat consisted of an open grassland/prairie. Adjacent habitats were primarily a mix of immature deciduous woodland and a shallow wetland dominated by Reed Canary Grass (*Phalaris arundinacea*) and Cattail (*Typha* sp.). This observation supplements specimens collected by R. Van Koningsveld in 1971 from nearby locations in the town of Whitewater (Walworth Co.; HerpNet catalogue numbers MPM 18291, 18292, 18294, and 18302; http://www.herpnet.org; accessed 6 February 2013). Although Casper (*op. cit.*) mentioned that Walworth Co. populations may be comprised of *T. butleri* x *T. radix* hybrids and questioned the likelihood that they contained true BGS, our analyses suggest that the genetic composition of these populations should be re-assessed. Given the short distance between the site where our specimens originated and Van Koningsveld's nearby Walworth Co. site (~ 1 km), future genetic research may lead to the inclusion of Walworth Co. in the known distribution for this species in Wisconsin. *Thamnophis butleri* is currently listed as "Threatened" by the state of Wisconsin and information that better refines its distribution in the state is particularly valuable for managing this species.

JOSHUA M. KAPFER (e-mail: kapferj@uww.edu**)** and **KERRY KATOVICH**, Department of Biological Sciences, University of Wisconsin-Whitewater, Whitewater, Wisconsin 53091, USA; **GREGOR W. SCHUURMAN** and **RORI A. PALOSKI**, Wisconsin Department of Natural Resources-Bureau of Endangered Resources, 101 S. Webster St., PO Box 7921, Madison, Wisconsin 53707-7921, USA; **BRIAN L. SLOSS**, U.S. Geological Survey, Wisconsin Cooperative Fishery Research Unit, College of Natural Resources, University of Wisconsin-Stevens Point, Stevens Point, Wisconsin 54481, USA.

***THAMNOPHIS SIRTALIS SIRTALIS* (Eastern Gartersnake)**. USA: TENNESSEE: Weakley Co.: approx. 450 m E of TN Hwy 43 along the Brian Brown Memorial Greenway in Martin, Tennessee (36.3492°N, 88.8672°W; WGS 84). 21 April 2012. Tom Blanchard. Verified by A. Floyd Scott. Austin Peay State University (APSU 19253). New county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/reptatlas/, latest update 04 December 2012, accessed 18 January 2013).

TOM BLANCHARD, Department of Biological Sciences, University of Tennessee at Martin, Martin, Tennessee 38238, USA; e-mail: tblanch@utm.edu.

***TROPIDOCLONION LINEATUM* (Lined Snake)**. USA: NEW MEXICO: Eddy Co.: 14.5 km SW of Queen, 3.4 km E of Martine Ridge, 9.3 km N of Texas State Line, and 0.1 km SSW of El Paso Gap on New Mexico State Highway 137 in southwestern Eddy Co. (32.0843°N, 104.8359°W; WGS84), elev. 1677 m. 20 September 2012. Christopher Newsom. Verified by J. Tomasz Giermakowski. University of New Mexico Museum of Southwestern Biology (MSB 94444). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, New Mexico xix + 431 pp.).

Extends the known range by approximately 87 km SSE from the nearest known specimen from Chaves Co., New Mexico (AUM 22798) and approximately 109 km SE of a recently verified locality near Mayhill, Otero Co., New Mexico (MSB 72651, Murray et al. 2010. Herpetol. Rev. 41:519–520.). The specimen was observed at night.

Further Range Extensions for Reptiles and Amphibians from Papua New Guinea

The Papuan region—consisting of New Guinea, Bismarck Archipelago, the Solomon Islands, and associated islands—has one of the most speciose herpetofaunas on Earth, but much work remains to better understand the composition and distributions of its members. The region's complex geological history, involving multiple waves of accretionary as well as vicariant events (Davies 2012; Pigram and Davies 1987), has resulted in many species being confined to local landforms such as offshore islands or peripheral mountain ranges. This has led to high levels of narrow endemism in the area. Furthermore, the region's steep terrain and difficulty of access have significantly retarded the pace of survey work. These factors have hindered detailed understanding of the geographic distributions of the local megadiverse herpetofauna. As one indication of the poverty of our knowledge, a large percentage of these species remain known only from their type localities. This is especially true among the frogs, for which this applies to approximately 25% of the species (cf., IUCN 2012). However, given the high proportion of narrow-range endemics that inhabit the Papuan region, it is uncertain which of these species are truly narrowly endemic vs. merely poorly surveyed. Intensive survey work conducted in the past 15 years or so has resulted in improved understanding of the geographic distributions of scores of Papuan species (Günther 2003; Kraus 2010; Kraus and Allison 2004, 2006; Kraus and Shea 2005). Herein I report additional significant range records for species collected by me in the past few years. In some of these cases it is obvious that the species in question ranges quite widely, and in several instances I present records indicating a species to range beyond the limits of the distinctive geological landforms (usually isolated mountain ranges) from which it was first described. However, in a few other instances I present evidence of a general distribution across the original massif from which the species was first described, but evidence for wider distribution outside that massif remains lacking.

Politically, the records presented below include one new country record and 18 new provincial records. Biogeographically, they include five new island records and 16 records that are first reports for particular isolated mountain ranges. Four new records for higher-elevation species are important in that they show each species' range to span the low-elevation habitat of the Musa Valley in the southern Owen Stanley Range, an expanse of terrain that is presumably unsuitable for these species at present. Finally, four additional records are to new areas within the high-elevation habitats of the Suckling–Dayman Massif (south of the Musa Valley) for species that are likely to prove endemic to that massif and the adjacent high-elevation Mt. Simpson.

All specimen records are for Bernice P. Bishop Museum (BPBM) and use the WGS 84 datum. One photo voucher is at University of Michigan Museum of Zoology (UMMZ).

ANURA — FROGS

AUSTROCHAPERINA BASIPALMATA. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., Mindangua Stream, 3.6056°S, 143.4921°E, 410 m asl. 17–21 September 2009. F. Kraus and native villagers. BPBM 35476–85; 16.25 km W of Wewak, 3.5788°S, 143.5003°E, 227 m. asl. F. Kraus and local villagers. BPBM 35486–87. New provincial record and range extension of approximately 150 km to E from nearest locality in Torricelli Mts. (Zweifel 2000).

BARYGENYS ATRA. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Victory, along Ajoa River, 9.2388°S, 149.1356°E, 400 m asl. 29 September–4 October 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37100–12, 37118–21; SW slope Mt. Trafalgar, 9.2238°S, 149.1561°E, 187 m asl. 2–6 November 2011. F. Kraus, J. Anamiato, and local villagers. BPBM 39973–78. First record for Cape Nelson Range and range extension of 100 km to SE of Popondetta (Zweifel 1981).

BARYGENYS MACULATA. PAPUA NEW GUINEA: Milne Bay Prov.: W slope Mt. Dayman, vicinity Binigun, 9.7071°S, 149.2498°E, 900 m asl. 17–19 March 2012. F. Kraus, E. Gagomin, B. Iova, and local villagers. BPBM 38914–15. Second known locality and range extension approximately 25 km to NNW of type locality on the other side of Mt. Dayman (Menzies and Tyler 1977).

CALLULOPS DORIAE. PAPUA NEW GUINEA: Milne Bay Prov.: Normanby Island, E end Sewa Bay, 10.0072°S, 150.9872°E, 52 m asl. 13 April 2011. F. Francisco. BPBM 38830–32. First record for any of the D'Entrecasteaux Islands (Zweifel 1972).

COPHIXALUS BALBUS. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., Mindangua Stream, 3.6056°S, 143.4921°E, 410 m asl. 16–19 September 2009. F. Kraus and local villagers. BPBM 35458–59, 35461–62, 35469. New record for mountain range and range extensions of approximately 125 km to NE and 150 km to E from nearest localities in Hunstein Mts. and Torricelli Mts., respectively (Kraus and Allison 2006).

COPHIXALUS CRYPTOTYMPANUM. PAPUA NEW GUINEA: Milne Bay Prov.: N slope Mt. Simpson, Etakaba Creek, 10.0290°S, 149.5947°E, 1540 m asl. 1 March 2003. B. Uruwa. BPBM 17959–74. Range extension of 40 km to SE from type locality (Zweifel 1956) and only second certain locality for this species. Based on call information, other populations to the north (Menzies 2006; Zweifel 1962) are mis-assigned to this species.

COPHIXALUS DESTICANS. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Victory, along Ajoa River, 9.2248°S, 149.1062°E, 530 m asl. 20–22 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37153–70; S slope Mt. Victory, 9.2388°S, 149.1356°E, 400 m asl. 27–29 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37171–72; SW slope Mt. Trafalgar, 9.2238°S, 149.1561°E, 187 m asl. 2–9 November 2011. F. Kraus, J. Anamiato, and local villagers. BPBM 40020–21, 40024, 40028,

FRED KRAUS
Department of Ecology and Evolutionary Biology, University of Michigan, Ann Arbor, Michigan 48109, USA
e-mail: fkraus@umich.edu

40030–36; SW slope Mt. Trafalgar, 9.2002°S, 149.1596°E, 700 m asl. 5 November 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 40026–27. New provincial records and range extension of 160 km to NW of nearest reported localities in southern Milne Bay Province (Kraus and Allison 2009a).

COPHIXALUS PIPILANS. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., Mindangua Stream, 3.6056°S, 143.4921°E, 410 m asl. 17–21 September 2009. F. Kraus and local villagers. BPBM 35842–43, 35845–56. New provincial record and range extension of 250 km to W of nearest reported locality in the Adelbert Mts. (Zweifel 1980).

COPIULA FISTULANS. PAPUA NEW GUINEA: Madang Prov.: Adelbert Mts., Keki Lodge, 4.7048°S, 145.4042°E, 854 m asl. 30 September–6 October 2009. F. Kraus and I. Haguna. BPBM 35961–67, 35973–78, 35985; Northern Province: S slope Mt. Victory, 9.2388°S, 149.1356°E, 400 m asl. 4–5 October 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37223–31. The first locality is a new provincial record and range extension of approximately 270 km to NW of nearest locality south of the Saruwaged Range; the second is the first report for Cape Nelson and a range extension of 100 km SE of nearest locality at Popondetta (Menzies and Tyler 1977).

HYLARANA MILNEANA. PAPUA NEW GUINEA: Milne Bay Prov.: NW slope Mt. Dayman, Yamsiai, 9.6724°S, 149.2734°E, 120 m asl. 7 April 2011. F. Kraus, E. Gagomin, B. Iova, and local villagers. BPBM 39304–05; Northern Prov.: S slope Mt. Victory, along Ajoa River, 9.2248°S, 149.1062°E, 530 m asl. 21–24 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37007–09; S slope Mt. Victory, 9.2388°S, 149.1356°E, 400 m asl. 27 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37010–24. Range extensions of approximately 100 and 160 km to NW of nearest localities near Alotau and 140 km from nearest locality on western side of intervening Owen Stanley Range; the localities on Cape Nelson are new provincial records (Kraus and Allison 2007).

HYLARANA VOLKERJANE. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., Mindangua Stream, 3.6056°S, 143.4921°E, 410 m asl. 15–21 September 2009. F. Kraus and local villagers. BPBM 34755, 35536–37, 35542–43; Madang Prov. Adelbert Mts., Keki Lodge, 4.7048°S, 145.4042°E, 854 m asl. 6 October 2009. F. Kraus and I. Haguna. BPBM 35549. New provincial records and range extensions of 150 km and 320 km to E from nearest locality in Torricelli Mts. (Kraus and Allison 2006).

HYLARANA WALIESA. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Victory, 9.2388°S, 149.1356°E, 400 m asl. 28–29 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37038–41; SW slope Mt. Trafalgar, 9.2238°S, 149.1561°E, 187 m asl. 31 October – 5 November 2011. F. Kraus, J. Anamiato, and local villagers. BPBM 39920–27. First records for province and range extension of 160 km to NW of nearest known localities in mainland Milne Bay Province and 100 km from populations on Goodenough Island (Kraus and Allison 2007).

LIOPHRYNE DENTATA. PAPUA NEW GUINEA: Milne Bay Prov.: Normanby Island, N slope Mt. Hobia, 10.0777°S, 150.9896°E, 555 m asl. F. Kraus. 27 March–2 April 2012. BPBM 41916–23. First record for any offshore island in Milne Bay Province, and third reported locality (Zweifel 2000).

LIOPHRYNE MAGNITYMPANUM. PAPUA NEW GUINEA: Milne Bay Prov.: E slope Mt. Suckling, 9.7580°S, 149.1822°E, 1860 m asl. 23–28 March 2011. F. Kraus, E. Gagomin, B. Iova, and local villagers. BPBM 39307–24. First provincial record and range extension of 130 km to east of type locality (Kraus and Allison 2009b).

LITORIA ARFAKIANA. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Trafalgar, 9.1951°S, 149.1616°E, 833 m asl. 7 November 2011. F. Kraus. BPBM 40124–26. First provincial record and first record for Cape Nelson Range (Menzies 2006).

LITORIA GASCONI. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., Mindangua Stream, 3.6056°S, 143.4921°E, 410 m asl. 18–21 September 2009. F. Kraus and local villagers. BPBM 35422–31. First record for country, and range extension of approximately 570 km to the east of previous records in the Foja Mts. (Richards et al. 2009).

LITORIA HUNTORUM. PAPUA NEW GUINEA: West Sepik Prov.: Torricelli Mts.: Parkop, 6.5 km S Mt. Sapau summit, 3.4246ºS, 142.5187ºE, 416 m asl. 14 May 2005. Local villager. BPBM 23243. New mountain range and range extension of approximately 100 km to E of type locality (Richards et al. 2006).

LITORIA MICROMEMBRANA. PAPUA NEW GUINEA: Milne Bay Prov.: E slope Mt. Suckling, 9.7580°S, 149.1822°E, 1860 m asl. 23 March 2011. F. Kraus, E. Gagomin, B. Iova, and local villagers. BPBM 39425–26; Biniguni Bunua, 9.7650°S, 149.2176°E, 1730 m asl. 21 March 2011. F. Kraus, E. Gagomin, B. Iova, and local villagers. BPBM 39418–24. New provincial record and extends range 130 km to E of nearest known locality (Kraus and Allison 2006).

LITORIA OLLAURO. PAPUA NEW GUINEA: Milne Bay Prov.: Milne Bay Prov.: W slope Mt. Dayman, 9.7071°S, 149.2498°E, 900 m asl. 17 March 2011. F. Kraus and B. Iova. BPBM 39620–26. Second known locality and range extension approximately 25 km to NNW of type locality on the other side of Mt. Dayman (Menzies 1993).

NYCTIMYSTES PERSIMILIS. PAPUA NEW GUINEA: Milne Bay Prov.: E slope Mt. Suckling, Biniguni Bunua, 9.7650°S, 149.2176°E, 1730 m asl. 21 March 2011. F. Kraus, E. Gagomin, B. Iova, and local villagers. BPBM 39429–53; Sota, 9.7580°S, 149.1822°E, 1860 m asl. 23 March 2011. F. Kraus. BPBM 39454. Range extensions of approximately 15 km and 55 km to W of type locality on Mt. Dayman (Zweifel 1958) and prior record on Mt. Simpson (Kraus and Allison 2004), respectively.

OREOPHRYNE GEISLERORUM. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Victory, along Ajoa River, 9.2248°S, 149.1062°E, 530 m asl. 20–24 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37291–303; S slope Mt. Victory, 9.2388°S, 149.1356° E, 400 m asl. 30 September 2010. F. Kraus, J. Anamiato, and local villagers. BPBM 37304–08; SW slope Mt. Trafalgar, 9.2238°S, 149.1561°E, 187 m asl. 1 November 2011. F. Kraus, J. Anamiato, and local villagers. BPBM 40148. First records from Cape Nelson Range and range extension of 100 km to SE of Popondetta (Zweifel et al. 2003).

SQUAMATA — LIZARDS

CYRTODACTYLUS LORIAE. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Trafalgar, 9.1951°S, 149.1616°E, 833 m asl. 11–13

November 2011. F. Kraus and local villagers. BPBM 39792–95. First provincial record (Bauer and Henle 1994) and range extension of 130 km E of Mt. Obree, Central Province (FK, unpubl. data).

HYPSILURUS DILOPHUS. PAPUA NEW GUINEA: Milne Bay Prov.: Normanby Island, E end Sewa Bay, 10.0072°S, 150.9872°E, 52 m asl. 3 March 2011. F. Francisco. BPBM 39725. New island record (de Rooij 1915; Manthey and Denzer 2006).

HYPSILURUS MAGNUS. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., Huriak, 3.5846°S, 143.5007°E, 68 m asl. 23 September 2009. Local villager. BPBM 34769. New provincial record and fills gap of approximately 530 km between nearest northern-versant localities in Madang and West Sepik provinces (Kraus 2010).

PRASINOHAEMA PREHENSICAUDA. PAPUA NEW GUINEA: Milne Bay Prov.: E slope Mt. Suckling, Sota, 9.7580°S, 149.1822°E, 1860 m asl. 29 March 2011. Local villager. BPBM 39096. New provincial record and range extension of approximately 380 km SE of Mt. Kaindi (Gressitt and Nadkarni 1978) for this poorly known arboreal lizard, indicating that it likely inhabits the entire length of the Owen Stanley Range at appropriate elevations.

VARANUS JOBIENSIS. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Victory, 9.2424°S, 149.1350°E, 320 m asl. 30 September 2010. Local villager. BPBM 37714. New provincial record and range extension of approximately 160 km E of Port Moresby (Böhme et al. 1994).

SQUAMATA — SNAKES

ASPIDOMORPHUS SCHLEGELI. PAPUA NEW GUINEA: East Sepik Prov.: Prince Alexander Mts., 17.2 km W and 1 km S Wewak, 3.5922°S, 143.4937°E, 270 m asl. 18 September 2009. Local villager. BPBM 35954. New provincial record and range extension 140 km E of nearest record at Aitape (McDowell 1967).

CANDOIA CARINATA. PAPUA NEW GUINEA: Northern Prov.: S slope Mt. Trafalgar, 9.2340°S, 149.1541°E, 223 m asl. 2 November 2011. Local villager. BPBM 39803. New provincial record, first record for Papuan Peninsula, and range extension of 360 km SE of nearest locality at Lae (Smith et al. 2001).

LEIOPYTHON ALBERTISII. PAPUA NEW GUINEA: Milne Bay Prov.: S end Sewa Bay, 10.03858°S, 150.97345°E, 54 m asl. 4 March 2011. Local villager. BPBM 39682; Northern Prov.: SW slope Mt. Trafalgar, 9.2238°S, 149.1561°E, 187 m asl. 9 November 2011. Local villager. BPBM 39805. Former is first verified record for D'Entrecasteaux Islands; latter is first record for Cape Nelson Range (Schleip 2008).

MORELIA BOELENI. PAPUA NEW GUINEA: Milne Bay Prov.: Gayari, W slope Mt. Dayman, ca. 1700 m asl. 3 April 2011. Local villager. Photographic voucher UMMZ Division of Reptiles and Amphibians digital image #972. First verified record for province and range extension of approximately 110 km to E of Mt. Brown (McDowell 1975), across the intervening low-elevation (maximum ca. 1000 m asl) Musa Valley. The source for a reported record from nearby Goodenough Island (O'Shea 1996) is uncertain (M. O'Shea, pers. comm.) and requires confirmation.

RAMPHOTYPHLOPS BRAMINUS. PAPUA NEW GUINEA: Milne Bay Prov.: Woodlark Island, Upper Muniai Creek, 9.1216°S, 152.7486°E, 67 m asl. 17 October 2011. Local villager. BPBM 39807. New island record and second record for province (Kraus and Allison 2004).

Acknowledgments.—I thank J. Anamiato, M. Asiyar, E. Clapp, G. Clapp, E. Gagomin, I. Haguna, G. Hast, F. Hurahura, B. Iova, A. Kakayo, J. Kakayo, W. Nemani, M. Okira, D. Seboma, C. Wintawa, B. Yawi, and Woodlark Mining Company for providing logistical or field assistance; the many local villagers at each visited site who provided field assistance or specimens; M. Hagemann, P. Imada, and T. Lopez for specimen processing and documentation; the Papua New Guinea National Museum and Art Gallery for providing in-country collaborative assistance; and the Department of Environment and Conservation, National Research Institute, and East Sepik, Madang, Milne Bay, and Northern provincial governments for research permits. This research was supported by National Science Foundation grants DEB-0103794 and 0743890.

Noteworthy Distributional Records of Amphibians and Reptiles from Costa Rica

Costa Rica is known to support a diverse herpetofauna (Savage 2002). According to the most recent checklist (Bolaños et al. 2011), 196 species of amphibians and 239 species of reptiles are known to occur in that country. During several visits to Costa Rica during 2010 and 2011, GK and JV have collected several specimens that constitute extensions of their known distributions in either geographic or elevational range. Herein we report upon these noteworthy specimens. Locality and elevation data were recorded using a Garmin 60 CSx GPS receiver with integrated barometric altimeter; map datum WGS84. Abbreviations for museum collections follow those of Sabaj Pérez (2010). Species determination was done using the keys in Köhler (2008, 2011) and Savage (2002), and all vouchers were verified by Sebastian Lotzkat and Andreas Hertz.

ANURA — FROGS

ECNOMIOHYLA SUKIA. ALAJUELA: SAN CARLOS, CERRO CHATO (10.2632°N, 84.4052°W), 922 m elev. 16 May 2012. Joseph Vargas. SMF 94578 (Fig. 1). First record for Alajuela Province, extending the species' known geographic distribution 147 km NE of Guayacan, Limón Province (Savage and Kubicki 2010).

ISTHMOHYLA PSEUDOPUMA. ALAJUELA: Volcán Tenorio (10.7048°N, 85.0305°W), 1143 m elev. 5 March 2011. Gunther Köhler and Joseph Vargas. SMF 91989–92. GUANACASTE: Volcán Miravalles (10.7060°N, 85.1107°W), 1225 m elev. 22 October 2011. Gunther Köhler and Joseph Vargas. SMF 94596. Volcán Rincón de la Vieja (10.8362°N, 85.3284°W), 1340 m elev. 27 October 2011. Gunther Köhler and Joseph Vargas. SMF 94597. First records for Volcán Tenorio and for Guanacaste Province, and also northernmost records for this species, extending its geographic range about 50 km NNW (Volcán Tenorio), 59 km NNW (Volcán Miravalles), and 82 km NW (Volcán Rincón de la Vieja), respectively, of Monteverde, Puntarenas (Duellman 2001; Savage 2002).

PHYLLOBATES VITTATUS. PUNTARENAS: Punta Burica, Río Coco (8.1807°N, 83.0149 °W), 390 m elev. 19 February 2011. Joseph Vargas. SMF 93576. Southeasternmost record for the species, extending its geographic range about 18 km S of previous southernmost record at Conte, 6 km E Puerto Pilon (UCR 9311) (Savage 2002; Savage, pers. comm., April 2013).

PRISTIMANTIS ALTAE. GUANACASTE: Volcán Miravalles (10.7084°N, 85.1180°W), 1400 m elev. 23 October 2011. Gunther Köhler and Joseph Vargas. SMF 94593–94 (Fig. 2). First record for Volcán Miravalles, filling the gap between Monteverde (ca. 59 km SSE), and Cerro Cacao (ca. 42 km WNW) (Savage 2002; Köhler 2011). Also, this record increases the previously known elevation for the species 140 m (Sasa et al. 2010).

SQUAMATA — LIZARDS

DIPLOGLOSSUS BILOBATUS. GUANACASTE: Volcán Miravalles (10.7044°N, 85.1136°W), 1215 m elev. 21–23 October 2011. Gunther Köhler and Joseph Vargas. SMF 94583–85. First records for Volcán Miravalles, filling the gap between Monteverde (ca. 59 km SSE), and Cerro Cacao (ca. 42 km WNW) (Savage 2002).

ANOLIS KEMPTONI. PUNTARENAS: N of Buenos Aires (9.2525°N, 83.2283°W), 1834 m elev. 6 February 2010. Gunther Köhler. SMF 92547. This record extends the species' geographic range about 65 km WNW from Las Tablas, Puntarenas (Savage 2002; Ponce and Köhler 2008).

ANOLIS INTERMEDIUS. SAN JOSÉ: Río Blanco (9.6469°N, 83.8876°W), 2110 m elev. 18 February 2010. Gunther Köhler. SMF 92597. This record increases the documented elevation of the species, which was previously known from as high as 1950 m (Sasa et al. 2010).

ANOLIS WOODI. ALAJUELA: Volcán Tenorio (10.7056°N, 85.0308°W), 1164 m elev. 6 March 2011. Gunther Köhler and Joseph Vargas. Photo voucher F-SMF 238 (Fig. 3). GUANACASTE: Volcán Miravalles (10.7101°N, 85.1205°W), 1460 m elev. 25 October 2011. Gunther Köhler. SMF 94586. First record for Guanacaste and northernmost records for this species, extending its geographic range about 50 km NNW (Volcán Tenorio) and 59 km NNW (Volcán Miravalles), respectively, of Monteverde, Puntarenas (Savage 2002).

ANOLIS TROPIDOLEPIS. CARTAGO: Hotel Tapanti (9.6787°N, 83.8927°W), 2520 m elev. 12 February 2010. Gunther Köhler. SMF 93627; HEREDIA: Cerro Chompipe (10.0978°N, 84.0729°W), 2613 m elev. 23 March 2010. Gunther Köhler. SMF 93668-69; SAN JOSÉ: Road between Copey and Providencia (9.6101°N, 83.9087°W), 2540 m elev. 21 February 2010. Gunther Köhler. SMF 93642. These records increase the documented elevation of the species, which was previously known from as high as 2506 m (Sasa et al. 2010).

PTYCHOGLOSSUS PLICATUS. ALAJUELA: Volcán Miravalles (10.7459°N, 85.1116°W), 1200 m elev. 25 October 2011. Gunther Köhler and Joseph Vargas. SMF 94592 (Fig. 4). This record extends the species' geographic range about 70 km NW of its closest known locality in the Cordillera de Tilarán, Alajuela (Savage 2002).

SPHENOMORPHUS CHERRIEI. ALAJUELA: Volcán Miravalles (10.7064°N, 85.1170°W), 1330 m elev. 21 October 2011. Gunther Köhler. SMF 94587. PUNTARENAS: Santa Elena, Sunset Hotel (10.3270°N, 84.8236°W), 1420 m elev. 28 October 2011. Gunther Köhler. SMF 94590. These records increase the documented elevation of the species in Costa Rica, which was previously known from as high as 1200 m (Sasa et al. 2010).

SQUAMATA — SNAKES

DENDROPHIDION PAUCICARINATUM. GUANACASTE: Volcán Miravalles (10.7060°N, 85.1168°W), 1220 m elev. 24 October 2011. Gunther Köhler. SMF 94576 (Fig. 5). First record for Volcán Miravalles, filling the gap between Monteverde (ca. 59 km SSE), and Cerro Cacao (ca. 42 km WNW) (Savage 2002).

GEOPHIS BRACHYCEPHALUS. HEREDIA: Volcan Barva, Las Tres Marias (10.1031°N, 84.1060°W), 2230 m elev. 28 February 2010. Gunther Köhler. SMF 94577. This record increases the documented known elevation of the species, which was previously known from as high as 2115 m (Wilson and Johnson 2010).

GEOPHIS ZELEDONI. HEREDIA: Volcan Barva, Las Tres Marias (10.1029°N, 84.1034°W), 2230 m elev. 28 February 2010. Gunther Köhler. SMF 92528. Volcan Barva, Los Angeles de Paso Llano (10.1077°N, 84.1033°W), 2260 m elev. 24 February 2010. Gunther Köhler. SMF 92524–27 (Fig. 6). These records increase the documented elevation of the species, which was previously known from as high as 2100 m (Wilson and Johnson 2010).

RHADINAEA DECORATA. PUNTARENAS: Punta Leona, Sendero Gigante (9.702660°N, 84.649400°W), 70 m elev. 4 March 2010. Gunther Köhler. SMF 92535. This record extends the species' geographic range along the Pacific versant about 159 km WNW from Boruca, Puntarenas (Myers 1974; Savage 2002).

PSEUSTES POECILONOTUS. PUNTARENAS: Las Tablas (8.926750°N, 82.785400°W), 1610 m elev. 18 March 2010. Gunther Köhler and Joseph Vargas. SMF 92538. This record increases the documented elevation of the species which was previously known from as high as 1330 m (Wilson and Johnson 2010).

SIBON LONGIFRENIS. ALAJUELA: Volcán Miravalles (10.7478°N, 85.1095°W), 1030 m elev. 25 October 2011. Gunther Köhler. SMF 94598 (Fig. 7). First record for Volcán Miravalles, filling the gap between Monteverde (ca. 59 km SSE), and Cerro Cacao (ca. 42 km WNW) (Savage 2002), respectively, and highest documented elevation for the species, which was previously known from as high as 750 m (Wilson and Johnson 2010).

TRIPANURGOS COMPRESSUS. PUNTARENAS: Punta Banco, Cerro Incendio (8.3613°N, 83.1224°W), 300 m elev. 22 February 2011. Joseph Vargas. SMF 93056 (Fig. 8). Southeasternmost record of this species in Costa Rica extending its geographical range about 30 km of the previous southernmost record at Quebrada Corosol near Golfito (UCR 11645) (Savage 2002; Savage, pers. comm., April 2013).

Acknowledgments.—Collecting and exportation permits were issued by Javier Guevara Sequeira, SINAC Central, Ministerio de Ambiente, Energía y Telecomunicaciones (MINAET), San José, Costa Rica. For field assistance, we thank Markus Gutpelet and Donald Varela Soto. We also thank Jay Savage for providing locality information on some Costa Rican amphibians and reptiles relevant to this article.

Amphibians and Reptiles of Jasper County, Mississippi, with Comments on the Potentially Extinct Bay Springs Salamander (*Plethodon ainsworthi*)

The Bay Springs Salamander (*Plethodon ainsworthi*) is a plethodontid salamander known from only two museum specimens collected in 1964 from a single locality in Jasper County, Mississippi, USA (Lazell 1998). Throughout the 1990s, numerous collection efforts were undertaken at the type locality and other nearby sites, utilizing diurnal searches, cover boards, and, on one occasion, a nocturnal search. To date, however, no searches have occurred during rainy nights or used drift fence arrays, the presumed optimal detection methods (Lazell 2005). Because no further individuals were found, the species is presumed to be extinct (Hammerson 2004).

Despite receiving considerable attention for *P. ainsworthi*, the amphibians and reptiles of Jasper County, Mississippi remain undersampled. Because no comprehensive county-by-county distributional lists or maps currently exist for Mississippi (Cliburn 1976; Lohoefener and Altig 1983), we compiled data from museum records and the published literature to address the historic occurrence of species in the county. We identified only 37 species historically documented from Jasper County: 34 by museum specimens and three solely by literature records (Table 1).

We conducted a bioblitz of amphibians and reptiles of Jasper County. Bioblitz competitions are survey events in which biologists compete to document the most species of defined taxa in a particular area (e.g., Graham et al. 2007; Graham et al. 2010a, 2010b). The objectives of the bioblitz were to: 1) search for the potentially extinct *P. ainsworthi* and 2) document new records to supplement the list of known species for the county. Because only a single effort has been conducted for *P. ainsworthi* at night to date, we aimed to utilize nocturnal searches to detect this species (Lazell 2005).

From 19–22 April 2012, eight individuals in two teams searched suitable habitat in public and private lands (with landowners' permission) throughout Jasper County. In particular, the Tallahala Wildlife Management Area provided a large area of diverse habitats. Situated in the transitional zone from upper to lower coastal plain (specifically, areas of the Pine Hills and Jackson Prairies physiographic provinces [Lowe 1921; Lohoefener and Altig 1983]), characteristic vegetation in Jasper County includes mixed agricultural areas, pine, and hardwood forests. Extensive diurnal and nocturnal searches were undertaken at the Ainsworth spring, the type locality of *P. ainsworthi*. Amphibian and reptile species were detected by visual encounter surveys, searching cover objects, road driving, and call surveys.

Extensive diurnal and nocturnal searches to locate *P. ainsworthi* were unsuccessful at the type locality and other nearby springs. During these searches, three salamander species were observed active at the surface of leaf-litter: *Eurycea cirrigera* (Southern Two-lined Salamander), *Eurycea guttolineata* (Three-lined Salamander), and *Desmognathus conanti* (Spotted Dusky Salamander). *Plethodon mississippi* (Mississippi Slimy Salamander) and *Pseudotriton ruber* (Red Salamander) were found under cover. No precipitation occurred during our searches (the most recent rain was three days prior), and the region was experiencing a cold front. Daytime high temperatures reached only approximately 17°C and nighttime lows were around 9°C. This effort represents only the second documented attempt to locate *P. ainsworthi* by searching at night. Perhaps future nocturnal efforts in conjunction with wet weather conditions could rediscover this presumably extinct species (Lazell 2005).

Thamnophis sauritus	Ribbon Snake	CM 2562	—
Virginia striatula	Rough Earth Snake	MCZ 192989	—
Sistrurus miliarius	Western Pygmy Rattlesnake	FMNH 3074	—

* Refer to literature records.

The Ainsworth spring appears to be in poor condition. The stream channel is heavily incised, likely as a result of ridge top deforestation and subsequent topsoil deposition, and Chinese Privet (*Ligustrum sinense*) is abundant. We recommend future searches in areas other than the type locality, since, despite the persistence of other plethodontid salamanders there, it seems degraded.

However, during our survey we detected 19 species of amphibians and 26 species of reptiles in Jasper County. Of these 45 species, 20 have not been collected from the county and represent new records. Two additional species were previously only represented by literature records, and we obtained the first museum specimens. Our bioblitz increases the list of amphibian and reptiles species known from Jasper County, Mississippi from

37 to 57. Records were vouchered as specimens or digital photographs, and deposited in the Herpetological Collections of the Auburn University Museum (AUM/AHAP). All records were verified by Craig Guyer. The datum for all GPS coordinates is WGS 84.

CAUDATA — SALAMANDERS

***EURYCEA cf. CHAMBERLAINI* (Chamberlain's Dwarf Salamander)**. Spring south of County Road (CR hereafter) 215 (31.89891°N, 89.20602°W). 21 April 2012. S. Graham and B. Folt. AUM 39665. A literature record for *Eurycea quadridigitata* (Dwarf Salamander) exists from "near Laurel" in Jasper County (Boyd and Vickers 1963). We found an individual from this species complex which was morphologically consistent with the description of *Eurycea chamberlaini* (e.g., the animal has a completely yellow ventral surface). However, a recent molecular analysis of the *E. quadridigitata* complex found support for an undescribed central lineage in Alabama and Georgia (Lamb and Beamer 2012), and this specimen likely belongs to that lineage. Tail tissue from this specimen was sent to D. Beamer, and future studies with more complete sampling are needed to resolve the taxonomy of the dwarf salamander complex.

***NOTOPHTHALMUS VIRIDESCENS* (Eastern Newt)**. Bienville National Forest, Tallahala Wildlife Management Area, floodplain east of W. Tallahala Creek and west of unnamed Forest Service road (32.17347°N, 89.31175°W). 20 April 2012. D. Laurencio and B. Folt. AUM 39844. Eft found surface active.

ANURA — FROGS

***HYLA AVIVOCA* (Bird-voiced Treefrog)**. Pond off CR 16 near W. Tallahala Creek (32.09298°N, 89.28417°W). 20 April 2012. B. Folt and D. Laurencio. AUM 39863. Male collected calling along edge of swamp.

***HYLA CHRYSOSCELIS* (Cope's Gray Treefrog)**. Pond off CR 16 near W. Tallahala Creek (32.09298°N, 89.28417°W). 20 April 2012. D. Laurencio and B. Folt. AHAP-C 0012. Calling male.

***LITHOBATES CATESBEIANUS* (American Bullfrog)**. Bienville National Forest, Tallahala Wildlife Management Area, CR 24, eastmost bridge near Quarterliah Creek (32.20348°N, 89.25446°W). 19 April 2012. B. Folt and D. Laurencio. AHAP-D 00507.

***LITHOBATES SPHENOCEPHALUS* (Southern Leopard Frog)**. Swamp off CR 16 near W. Tallahala Creek (32.09298°N, 89.28417°W). 19 April 2012. B. Folt and D. Laurencio. AUM 39868.

TESTUDINES — TURTLES

***CHELYDRA SERPENTINA* (Snapping Turtle)**. Junction of SR 18 & CR 1822 (32.12635°N, 89.02720°W). 21 April 2012. S. Graham. AHAP-D 00508. Dead on road.

***CHRYSEMYS DORSALIS* (Southern Painted Turtle)**. Bienville National Forest, Tallahala Wildlife Management Area, Quarterliah Creek at CR 24 (32.20343°N, 89.25914°W). 22 April 2012. B. Folt and S. Graham. AHAP-D 00511. Adult basking on log.

***PSEUDEMYS CONCINNA* (River Cooter)**. Bienville National Forest, Tallahala Wildlife Management Area, Quarterliah Creek at CR 24 (32.20343°N, 89.25914°W). 19 April 2012. B. Folt and D. Laurencio. AHAP-D 00512. Adult photographed basking on log in creek.

***STERNOTHERUS MINOR PELTIFER* (Stripe-necked Musk Turtle)**. Juncture of Tallahoma Creek and CR 8/SR537 (31.83338°N, 89.15817°W). 22 April 2012. S. Graham. AHAP-D 00509.

***TRACHEMYS SCRIPTA* (Pond Slider)**. Cedar Creek at CR 24 (32.20047°N, 89.30022°W). 20 April 2012. B. Folt. AHAP-D 00510. Juvenile hand captured in creek.

SQUAMATA — LIZARDS

***PLESTIODON FASCIATUS* (Common Five-lined Skink)**. Bienville National Forest, Tallahala Wildlife Management Area, forest south of CR 24 (32.20267°N, 89.27019°W). 21 April 2012. S. Goetz and J. Goessling. AUM 39840.

***SCINCELLA LATERALIS* (Little Brown Skink)**. Culvert off CR 2414 (32.16584°N, 89.07288°W). 19 April 2012. B. Folt and D. Laurencio. AUM 39869. Adult collected at night. A literature record exists for this species in the county (Cliburn 1959), but our collection provides the first verifiable museum specimen.

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead)**. SR 503 near junction with CR 20 (32.13914°N, 89.06058°W). 19 April 2012. B. Folt and D. Laurencio. AUM 39901. Collected injured on road.

***AGKISTRODON PISCIVOROUS* (Cottonmouth)**. Bienville National Forest, Tallahala Wildlife Management Area, CR 24 at Quarterliah Creek (32.20348°N, 89.25446°W). 19 April 2012. B. Folt and D. Laurencio. AHAP-D 00518.

***COLUBER CONSTRICTOR* (North American Racer)**. Bienville National Forest, Tallahala Wildlife Management Area, CR 24 at Quarterliah Creek (32.20348°N, 89.07288°W). 19 April 2012. D. Laurencio and B. Folt. AHAP-D 00515.

***COLUBER FLAGELLUM* (Coachwhip)**. Rocky Mount Cemetery near CR 52814 (32.00931°N, 89.08140°W). 22 April 2012. S. Graham. AUM-S 0001.

***NERODIA ERYTHROGASTER* (Plain-bellied Watersnake)**. Bienville National Forest, Tallahala Wildlife Management Area, CR 24 at Quarterliah Creek (32.20348°N, 89.25446°W). 19 April 2012. B. Folt and D. Laurencio. AUM 39867.

***NERODIA RHOMBIFER* (Diamond-backed Watersnake)**. CR 24 at Cedar Creek (32.19994°N, 89.31655°W). 22 April 2012. S. Graham and B. Folt. AHAP-D 00516.

***STORERIA DEKAYI* (DeKay's Brownsnake)**. Bienville National Forest, Tallahala Wildlife Management Area, forest south of CR 24 (32.20325°N, 89.26417°W). 21 April 2012. J. Goessling, S. Goetz, and B. Folt. AUM 39852.

***STORERIA OCCIPITOMACULATA* (Red-bellied Snake)**. Bienville National Forest, Tallahala Wildlife Management Area, forest off CR 23 (32.17161°N, 89.26458°W). 21 April 2012. J. Goessling and S. Goetz. AUM 39861.

***VIRGINIA VALERIAE* (Smooth Earthsnake)**. Bienville National Forest, Tallahala Wildlife Management Area, forest off CR 23 (32.17161°N, 89.26458°W). 21 April 2012. J. Goessling, S. Goetz. AUM 39862.

Acknowledgments.—We thank the landowners for allowing access to private properties, Scott Peyton of the Mississippi Museum of Natural Science for assistance in procuring the proper permits (MS Scientific Collecting Permit #0412121) and museum data, Craig Guyer for verifying all records, and Auburn University librarians for procuring literature resources for this study.

As part of an ongoing study examining the ecological integrity of seasonal wetlands in the state of Illinois, we sampled 117 wetlands for the presence of amphibians and reptiles on state managed properties in east-central Illinois. Since the publication of Phillips et al. (1999), multiple articles documenting new county records from our study region have appeared in *Herpetological Review* (Foster and Mullin 2007; Petzing et al. 1998, 2000, 2002, 2007, 2008). These publications presented a large number of new county records for this once poorly sampled region. With the extensive sampling required by this new study, we were able to document some less commonly encountered species in the region. Herein we report 17 specimens that represent new county records in the state of Illinois. All vouchered specimens are housed at the Illinois Natural History Survey (INHS) amphibian and reptile collection while unvouchered specimens are represented by a digital image in the Non-INHS Unvouchered Illinois Herps Database (Unvouch). County records were confirmed using the Illinois Herpetological Database at the INHS, which contains records of Illinois amphibians and reptiles from 30 museums collections as well as a collection of digital images of unvouchered specimens and observations from herpetologists and state biologists, and by examining volumes of *Herpetological Review* published since Phillips et al. (1999). Coordinates are presented in decimal degrees using map datum WGS84. Scientific and common names follow Crother (2012).

CAUDATA — SALAMANDERS

***AMBYSTOMA LATERALE/JEFFERSONIANUM* (unisexual allotriploid [JJL] combining genomes of *A. jeffersonianum* and *A. laterale*)**. Crawford Co.: Crawford County Conservation Area; 3.4 km NW of Trimble (39.08635°N, 87.71039°W). 16 March 2010. A. R. Kuhns, T. L. Esker, W. J. B. Anthonysamy, J. Gillespie. Verified

by W. E. Peterman (University of Missouri-Columbia) by gel electrophoresis using AjeD94, AjeD346, and AjeD212 microsatellite primers (Julian et al. 2003). INHS 21629. This specimen was one of six individuals captured in minnow traps from ponds created at the site in 2005.

Salamanders of the *Ambystoma laterale/jeffersonianum* complex are considered endangered and therefore are afforded protection by the Illinois Endangered Species Protection Board (Nyboer et al. 2006). Unisexual allotriploids were previously known from only a small handful of ponds in the Middle Fork Vermilion River drainage, northeast of Oakwood, Vermilion Co., Illinois. This new record is 120 km from the other known location of known allotriploids in Illinois. Although extensive sampling for ambystomatid salamanders has occurred in the region (Peterman et al. 2013), no allotriploids have been documented between these two locations in Illinois.

***AMBYSTOMA MACULATUM* (Spotted Salamander).** Lawrence Co.: Red Hills State Park; 6.2 km WNW of Bridgeport (38.7181°N, 87.83023°W). 7 March 2012. J. A. Crawford, E. J. Kessler, A. R. Kuhns, and C. A. Phillips. Verified by D. B. Wylie. INHS 22727. Adult captured in drift fence beside a recently created ephemeral pond.

***AMBYSTOMA TEXANUM* (Small-mouthed Salamander).** Shelby Co.: Eagle Creek State Park; 3.5 km ESE of Findlay (39.50555°N, 88.71979°W). 1 May 2012. J. A. Crawford, E. J. Kessler, A. R. Kuhns, and C. A. Phillips. Verified by D. B. Wylie. INHS 22809. Adult caught in pitfall trap.

***AMBYSTOMA TIGRINUM* (Tiger Salamander).** Crawford Co.: Crawford County Conservation Area; 3.4 km NW of Trimble (39.08635 -87.71039). 16 March 2010. A. R. Kuhns, T. L. Esker, W. J. B. Anthonysamy, and J. Gillespie. Verified by D. B. Wylie. INHS 21628. This specimen was one of four individuals captured in minnow traps from an ephemeral pond created in 2005.

***PLETHODON GLUTINOSUS* (Northern Slimy Salamander).** Jasper Co.: Prairie Ridge State Natural Area; 3.6 km NNW of Bogota (38.94819°N, 88.25375°W). 9 May 2012. E. J. Kessler and J. A. Crawford. Verified by D. B. Wylie. INHS 22834. Adult found under log in woodland.

***SIREN INTERMEDIA* (Lesser Siren).** Jasper Co.: Simpson Property; 2.1 km WNW of Yale (39.13012°N, 88.04545°W). 12 April 2012. J. A. Crawford and E. J. Kessler. Verified by D. B. Wylie. INHS 22777. Adult captured in minnow trap in ephemeral pond created in 2010.

Wayne Co.: Sam Dale Lake State Conservation Area; 10.9 km SSE of Xenia (38.54289°N, 88.59354°W). 9 May 2012. C. A. Phillips, E. M. Wright, and L. L. Jacques. Verified by D. B. Wylie. INHS 22835. Adult caught in minnow trap in ephemeral pond.

ANURA — FROGS

***LITHOBATES SYLVATICUS* (Wood Frog).** Fayette Co.: Ramsey Lake State Park; 1.9 km NW of Ramsey (39.15422°N, 89.12731°W). 7 June 2012. R.S. Saffer and E.M. Wright. Verified by D. B. Wylie. INHS 22928. Juvenile captured in pitfall trap near ephemeral pond.

Lawrence Co.: Red Hills State Park; 6.4 km WNW of Bridgeport (38.71948°N, 87.83178°W). 7 March 2012. J. A. Crawford, E. J. Kessler, A. R. Kuhns, and C. A. Phillips. Verified by D. B. Wylie. INHS 22728. Adult caught in a pitfall trap near an ephemeral pond.

TESTUDINES — TURTLES

***STERNOTHERUS ODORATUS* (Eastern Musk Turtle).** Wayne Co.: Sam Dale Lake State Conservation Area; 10.6 km SSE of Xenia (38.54539°N, 88.59484°W). 16 February 2012. J. A. Crawford, B. Daugherty, and A. R. Kuhns. Verified by D. B. Wylie. INHS 22638. Shell found by small pond. Gravid adult female was also found DOR near pond at entrance to park on 13 June 2012.

Clark Co.: Lincoln Trail State Park 6.1 km SSW of Marshall. (39.33798°N, 87.71184°W). 28 June 2011. E. M. Wright. Verified by D. B. Wylie. Unvouch 42631. Adult female found in campground on the edge of the state park presumably searching for nesting habitat.

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider).** Moultrie Co.: Whitley Creek Recreation Area; 7.3 km SSW of Sullivan (39.53607°N, 88.62716°W). 3 May 2012. E. J. Kessler, A. R. Kuhns, and C. A. Phillips. Verified by D. B. Wylie. INHS 22817. Juvenile found crossing park access road.

SQUAMATA — LIZARDS

***PLESTIODON FASCIATUS* (Common Five-lined Skink).** Shelby Co.: Eagle Creek State Park; 5.8 km SSE of Grandview (39.49142°N, 88.70842°W). 3 May 2012. E. J. Kessler and A. R. Kuhns. Verified by D. B. Wylie. INHS 22818. Found under log in woodlands between ephemeral pond and golf course.

***PLESTIODON LATICEPS* (Broad-headed Skink).** Lawrence Co.: Red Hills State Park; 6.1 km WNW of Bridgeport (38.72425°N, 87.82633°W). 17 May 2012. J. A. Crawford, A. R. Kuhns, and C. A. Phillips. Verified by D. B. Wylie. INHS 22925. Adult captured in drift fence beside ephemeral pond.

***SCINCELLA LATERALIS* (Little Brown Skink).** Marion Co.: Stephen A. Forbes State Recreation Area, 10.3 km SE of Kinmundy (38.71153°N, 88.75856°W). 12 June 2012. E. J. Kessler and L. L. Jacques. Verified by D. B. Wylie. INHS 22923. Adult found under piece of silt fencing while removing drift fence.

SQUAMATA — SNAKES

***HETERODON PLATIRHINOS* (Eastern Hog-nosed Snake).** Moultrie Co.: Whitley Creek Recreation Area, NW of Co. Hwy. 19 and Co. Rd. 900N (39.53608°N, 88.62781°W). 3 May 2012. E. J. Kessler, A. R. Kuhns, and C. A. Phillips. Verified by D. B. Wylie. INHS 22819. Juvenile captured in funnel trap placed along a drift fence.

***STORERIA DEKAYI* (Dekay's Brownsnake).** Jasper Co.: Sam Parr State Park; 5.8 km NE of Newton (39.02860°N, 88.11581°W). 22 June 2012. A. R. Kuhns, R. S. Saffer, and E. M. Wright. Verified by D. B. Wylie. INHS 22912. Adult captured in drift fence beside ephemeral pond.

Acknowledgments.—We thank Illinois District Natural Heritage Biologist Roger Jansen for making contact with land managers in his district and also for the use of field equipment. We also thank the

multiple IDNR land managers who granted us permission to conduct research in their parks and aided us in innumerable ways, especially Scott Simpson. Thanks also go to the Illinois Natural History Survey Museum Collections Manager Dan Wylie for cataloging and verifying specimens.

Field work was supported by United States Environmental Protection Agency Region 5 Wetlands Program Development Grants CD-00 E00740 and CD-00 E00963 and an IDNR Wildlife Preservation Fund Grant 09L-19W. Fieldwork was conducted under permits from the Illinois Department of Natural Resources to work on state managed properties, collecting permits to A. R. Kuhns and C. A. Phillips, and, when applicable, IDNR Endangered and Threatened Species Permit, 05-11S. Field sampling was conducted under University of Illinois Institutional Animal Care and Use Committee Protocols 10211 (to ARK) and 11203 (to CAP).

New Departmental Records for Amphibians and Reptiles in Honduras

From 30 June to 12 July 2011, we conducted a preliminary survey of the amphibians and reptiles on the islands in the Gulf of Fonseca, Department of Valle, in southern Honduras. McCranie (2007, 2011) had previously demonstrated that Valle was one of several departments that had been understudied regarding its amphibian and snake faunas, respectively. Two of us (JRM and LVO) also spent a week during April 2011 collecting in the Departments of Copán and Santa Bárbara in northwestern Honduras. McCranie (2007, 2011) had shown that Santa Bárbara was also under-studied in regards to its amphibian and snake faunas. During those surveys we documented one species of snake new to Honduras (*Tantilla vermiformis*) and new department records for one frog, two lizards, six other snakes, and one turtle. Identifications of USNM specimens were verified by Steve W. Gotte, those deposited in MVZ were verified by Sean M. Rovito, and UNAH vouchers were verified by Gustavo A. Cruz. Coordinates and elevations were taken with a GPS device using map datum WGS84.

ANURA — FROGS

***TRACHYCEPHALUS TYPHONIUS* (Veined Treefrog; Rana Trepadora Lechosa).** VALLE: Isla Garrobo (13.3169°N, 87.700126°W), 25 m elev. 7 July 2011. USNM 579695. Closest known locality for this species is ca. 30 km SE at Cedeño, Choluteca (McCranie 2006). The frog was active at night in a tree ca. 3 m above the ground in second growth dry forest.

SQUAMATA — LIZARDS

***HOLCOSUS UNDULATUS* (Rainbow Ameiva; Lagartija Metálica).** VALLE: Isla del Tigre, near communications tower (13.26678°N, 87.633412°W), 783 m elev. 30 June 2011. USNM 579690. Closest known locality for this species is ca. 65 km ENE on Cerro Guanacaure, Choluteca (SDSNH 72693, 72696, USNM 579539). The lizard was active on the ground at midday in an area denuded of its dry forest.

***IGUANA IGUANA* (Green Iguana; Iguana de Ribera).** VALLE: Isla de La Vaca (13.300024°N, 87.583562°W), 5 m elev. 9 July 2011. UNAH 5653. First published record from Valle, although Lovich et al. (2006) in an unpublished report, acknowledged a

photograph of this species from nearby Isla del Tigre. Nearest mainland records are from ca. 25 km SE at Cedeño, Choluteca (BYU 18289–300). The lizard was ca. 2 m above ground in a tree growing on a small cliff overlooking the Gulf of Fonseca.

SQUAMATA — SNAKES

***CONIOPHANES FISSIDENS* (Yellow-bellied Snake; Panza Amarilla)**. SANTA BÁRBARA: Quebrada Las Cuevas, Montaña El Joconal (15.053444°N, 88.517056°W), 1150 m elev. 19 April 2011. MVZ 267178. Closest known localities are from ca. 50 km SW at Dolores, Copán, and ca. 35 km ESE in the vicinity of El Jaral, Cortés (McCranie 2011). The snake was killed by a local resident on a coffee farm.

***ENULIUS FLAVITORQUES* (Pacific Long-tailed Snake; Coluda del Pacifico)**. VALLE: Isla Exposición (13.300212°N, 87.66690°W), 20 m elev. 8 July 2011. USNM 579683. Isla Inglesera (13.300248°N, 87.700033°W), near sea level to 15 m elev. 4, 5, and 12 July 2011. USNM 579684–86. Closest known locality to both islands is ca. 30 km SE at Cedeño, Choluteca (McCranie 2011). All snakes were active at night on the ground or in rock walls in denuded dry forest.

***IMANTODES CENCHOA* (Blunthead Tree Snake; Cordelilla Manchada)**. SANTA BÁRBARA: Quebrada Las Cuevas, Montaña El Joconal (15.053444°N, 88.517056°W), 1150 m elev. 19 April 2011. MVZ 267184. Closest known localities are from ca. 60 km SW at Santa Rosa de Copán, Copán, and ca. 40 km ESE at Agua Azul, Cortés (McCranie 2011). The snake was active at night on low vegetation in an area of moderately disturbed broadleaf forest.

LEPTODRYMUS PULCHERRIMUS. VALLE: Isla Comandante (13.283569°N, 87.616893°W), 2 m elev. 9 July 2011. USNM 579687. Closest known locality is ca. 80 km E at El Banquito, Choluteca (McCranie 2011). The snake was active at midday on the grounds of a resort previously covered by dry forest.

***OXYRHOPUS PETOLARIUS* (Calico False Coral Snake; Falsa Coral de Calico)**. COPÁN: San Isidro (15.116667°N, 88.933333°W), 1100 m elev. 26 April 2011. MVZ 267202. Closest known Honduran locality is ca. 115 km ESE in the vicinity of Lago de Yojoa, Cortés (McCranie 2011). The snake was under surface debris during the day in an area of highly disturbed broadleaf forest.

TANTILLA IMPENSA. SANTA BÁRBARA: El Cedral (14.916677°N, 88.066884°W), 1700 m elev. 29 April 2011. MVZ 267219. Closest reported localities are ca. 100 km WNW at Quebrada Grande, Copán, and ca. 15 km E at Lago de Yojoa, Cortés (McCranie 2011). The snake was inside a large rotten log on a coffee farm.

TANTILLA VERMIFORMIS. VALLE: Isla Exposición (13.300212°N, 87.666901°W), 20 m elev. 8 July 2011. (USNM 579681). First record for Honduras and first record for any island. The locality bridges the gap between Lago de Ilopango, San Salvador, El Salvador, ca. 160 km to the WNW (Köhler et al. 2005) and Chinandega, Nicaragua, ca. 95 km to the SE (Köhler 2001). McCranie (2011) had predicted that this species would eventually be found in Honduras as it was known from west and south of the country. The juvenile female (Fig. 1) was under a rock on a steep hillside surrounded by dry forest.

PHOTO BY A. GUTSCHE

FIG. 1. Juvenile female *Tantilla vermiformis* (total length 73 mm) from Isla Exposición, Valle, Honduras (USNM 579681).

TESTUDINES — TURTLES

***LEPIDOCHELYS OLIVACEA* (Olive Ridley Sea Turtle; Tortuga Golfina)**. VALLE: Isla Garrobo, small sandy beach on SW side of island (13.3169°N, 87.700126°W). 9 July 2011. UNAH 5654. Closest recorded locality is ca. 20 km E at Punta Ratón, Choluteca (UF 34483–517, 69895–905). In this case, an egg shell was found exposed on the beach, and according to locals, the site is infrequently used for nesting by this species.

Acknowledgments.—Collecting (Dictamen DVS-ICF-016-2009) and export (Constancia 042-2011-DVS-ICF) permits were issued by Iris Acosta, Carla Cárcamo, and Saíd Laínez of the Instituto Nacional de Conservación y Desarrolo Forestal, Áreas Protegidas y Vida Silvestre (ICF), Tegucigalpa, Honduras. Copies of these permits are on file at the USNM, Washington D.C. Voucher numbers were provided by Gustavo A. Cruz and Julio E. Mérida for UNAH specimens, Carol Spencer for MVZ specimens, and Steve W. Gotte for USNM specimens. We also thank Rodolfo Nuñez Pacheco and Maritza Roxana Bonilla Ochoa for their help with transportation and meals during our fieldwork in Valle.

NATURAL HISTORY NOTES

GYMNOPHIONA — CAECILIANS

***SCHISTOMETOPUM THOMENSE* (São Tomé Caecilian). PREDATION.** The caecilian *Schistometopum thomense* is endemic to the island of São Tomé, Central Africa. Its unusual bright yellow coloration makes it a familiar animal, locally known as 'cobra-bobo'(Measey and Van Dongen 2006. Evol. Ecol. Res. 8:1049–1059). This species has a wide distribution including anthropogenic habitats but little has been reported on the natural history of S. *thomense* in its natural environment (Nussbaum and Pfrender 1998. Misc. Publ. Mus. Zool., Univ. Michigan 187). Herein we report a direct observation of an adult domestic Muscovy Duck (*Cairina moschata*) predating on an adult S. *thomense*, the first predation record for this species. At 0630, 31 Oct 2012, we observed a domestic Muscovy Duck attempting to swallow a bright yellow *S. thomense* at the entrance of the main group of houses of the locality of Água Sampaio (00.3513°N, 06.6049°W), district of Lobata, São Tomé Island. The duck had already approximately half of the body length of the caecilian in its beak and unsuccessfully attempted to swallow it for about 30 seconds. The duck then carried the amphibian to a puddle of water where, with the help of this liquid, it finally managed to swallow the caecilian. We occasionally observed the duck during the next few hours in which it seemed to be unaffected and behaving normally. This report casts doubt on the hypothesis that the unusually bright coloration of *S. thomense* is aposematic and thus that the skin of *S. thomense* is toxic (Hofer 1998. Herpetozoa 11:37–46).

The field work during which this observation was made was funded by a 2nd Rufford Small Grant (11388-2). We would like to thank R. Lima and L. Viegas for field support and K. Schillinger for technical support.

CAUDATA — SALAMANDERS

***AMBYSTOMA BISHOPI* (Reticulated Flatwoods Salamander). EGG SURVIVAL AFTER FIRE.** Reticulated Flatwoods Salamanders are endemic to the fire-maintained Longleaf Pine (*Pinus palustris*)/Wiregrass (*Aristida stricta*) ecosystem of the Southeastern Coastal Plain of the United States. Adults migrate to ephemeral wetlands during fall and early winter (Palis 1997. J. Herpetol. 31:71–78), and females lay eggs on the ground before the wetland basin fills with water. Larvae develop within terrestrially deposited eggs, often for several weeks or months, and hatch upon inundation from winter rains (Anderson and Williamson 1976. Herpetologica 32:4–22; Pierson Hill, Florida State Univ., pers. com.; Kelly Jones, pers. obs.; Sylvia Powell, pers. obs.).

We observed live *Ambystoma bishopi* eggs in wetlands with dry basins from late December 2011 to late-February 2012 on Eglin Air Force Base, Okaloosa Co., Florida, USA. The fall-winter season was characterized by low rainfall, and the majority of the eggs we monitored were not inundated and did not hatch successfully. Most, but not all, of the monitored eggs were dead by late-February.

On 3 January 2012, B. Rincon found a group of at least six live eggs on the ground sheltered above by herbaceous plants (including the dead basal leaves of *Eriocaulon compressum* and a rosette of *Dichanthelium* sp.). Embryos visible within the eggs exhibited tails with bright skin coloration (Harrison stage between 35 and 45; Harrison 1969. Organization and Development of the Embryo. Yale Univ. Press, New Haven, Connecticut). Additional eggs might have been obscured behind others, because the egg deposition site was a recess of soil and vegetation (< 5cm deep), and we tried not to disturb the eggs.

FIG. 1. View of the area where *Ambystoma bishopi* eggs were laid as seen the day after a fire passed over the area. Living eggs were located here after the prescribed burn of the wetland, which occurred on 22 February 2012 in Okaloosa Co., Florida, USA.

On 19 February 2012, SDP again noted at least six eggs present at the location, including a moving embryo with eyes, tail, and gills (stage 37–46) in a partially open egg sac. The wetland had some scattered small puddles of water at the time. On 20 February, an embryo with forelimbs (stage 40–46) was moving within an intact egg; the soil was saturated with water but no standing water was present. Anticipating a prescribed fire at the location, a fire resistant marker (large bolt with washer) was placed ca. 10 cm from the eggs on the evening of 21 February. On the morning of 22 February, at least four live eggs were observed. Later that day, the wetland was burned by a prescribed fire that burned through the entire wetland, but did not consume all of the herbaceous plant material in areas with moist soil.

On the morning after the burn, two apparently healthy embryos were visible and one moved, but some embryos were clearly dead. Charred vegetation was present immediately above the eggs, indicating that fire passed directly over the eggs (Fig. 1). The dead embryos were closer to the charred vegetation at the surface, and their skins were grayish rather than brightly colored. The dead embryos had fully formed mouths (stage 43–46); one was measurable and was ca. 11.3 mm total length. Live eggs were present at the site as late as 25 February, when two embryos moved in partially open egg sacs and an intact egg with an apparently healthy embryo inside was nearby. All of the eggs were dead by 28 February.

Prescribed fires in pine flatwoods are usually implemented during the winter months when wetlands typically retain water (Bishop and Haas 2005. Nat. Areas J. 25:290–294). However, this prescribed fire was in an uncharacteristically dry wetland, so the fire successfully carried through the wetland. Based on our observations it appears that in some cases eggs laid terrestrially can survive fire. Additional observations of eggs before and after fires would be necessary to determine how fire may affect egg survival rates or influence populations.

SDP's fieldwork on Eglin Air Force Base was funded by a grant ("Experimental Restoration of Pine Flatwoods") from the Department of Defense Legacy Resource Management Program to Thomas Gorman and Carola Haas. We thank the field technicians and volunteers who assisted with locating and monitoring eggs, Robert Powell who made editorial comments, and the natural resource staff of Jackson Guard, Eglin Air Force Base for their support.

***AMBYSTOMA MAVORTIUM* (Barred Tiger Salamander). BEHAVIOR UNDERNEATH THE ICE.** Larval *Ambystoma mavortium* in North Dakota spend the winter months (late October–early April) restricted underneath a thick (0.5–1.3 m) ice sheet. During February and March 2012, we observed larval *A. mavortium* in Swalls Lake, Ward Co., North Dakota, USA (48.1044°N, 101.1644°W). We drilled holes in the ice using an ice auger equipped with 20.3 cm blade. We established three ice-hole grids. Each grid had nine holes in a 3 × 3 arrangement on a 20 × 20 m square (i.e., four holes were the corners of the square). Thus, we established 27 observation holes over three locations on the lake. We could drill and observe nine holes during a four-hour observation period. We completed four, four-hour observation periods before the ice became unsafe.

To make observations, we used an Aqua-Vu underwater 760 color camera equipped with video recorder. When salamanders were viewed among vegetation, we used an average cattail stem diameter of 11.8 mm for calibration using ImageJ to estimate salamander size. Water temperatures ranged from 2.2 to 3.0°C. Observation depths ranged from 0.2 to 2 m.

Because each hole is 10 m from the nearest hole, we assumed that the number of individual salamanders observed more than once during a visit was minimal. Visibility was estimated as 0.7 m in any direction, thus a full rotation of the camera covered a circular area with a radius of 0.7 m and a circular viewing area of 1.54 m^2. Given this viewing area at each hole, we observed 13.86 m^2 during each trip to the pond (i.e., nine holes, each 1.54 m^2). We viewed a total of 224 salamanders during our four observation periods (i.e., an average of 56 salamanders observed in an area of 13.85 m^2, or 4.04 salamanders/m^2). Using a total lake area of 45,285 m^2 provides a coarse winter population estimate of approximately 183,102 salamanders in Swalls Lake. This estimate falls within our previous catch-per-unit effort and PIT-tag mark-recapture estimates (Poitra et al. 2007. Proc. NDAS 61:15). Salamanders measured (N = 11) averaged 128.1 mm SVL (standard deviation 17.2). All observed salamanders were large (range 99.1–151.2 mm SVL).

The Amphibian Growth Project (AGP) has been monitoring Swalls Lake as part of a long term population monitoring program since 2005. Metamorphosis of *A. mavortium* at Swalls Lake occurs during August and September at ca. 98 mm SVL. Swalls Lake is a semipermanent wetland that last dried completely in the late 1980s. This wetland is irregular in shape and is surrounded by farm fields maintained by the North Central Research Extension Office of North Dakota State University. When full of water, the maximal depth in this wetland is 2.8 m. In summer months, the *Ambystoma* population at Swalls Lake consists of a mixed population of immature larvae, sexually mature larvae (i.e., paedomorphs), immature transformed salamanders, and sexually mature transformed salamanders (Poitra et al. 2007. *op. cit.*). We did not observe any transformed salamanders and it is likely that these salamanders that we viewed consist of both immature and mature larvae. Both salamanders with and without swollen cloacae were observed.

Most of the salamanders observed were active. No aggression among salamanders was observed. In several cases, the salamanders are crowded such that they are nearly always in contact with another salamander. Movement up and down in the water column was very common. We often observed salamanders slowly ascending to the top of the water column (i.e., to the bottom of the ice cover) and then swimming rapidly downwards. This is a behavior seen when salamanders gulp air from the surface during ice-free months. Lung deflation in amphibians occurs during long term restriction from surface area and can be a cause of significant mortality (Ultsch et al. 2004. Comp. Biochem. Phys. Part A 139:111–115). However, the salamanders were able to maintain position in the water with no effort, i.e., were buoyant. Therefore we suggest that these salamanders are able to maintain inflated lungs during the winter. We are unable to determine at this time if the salamanders are gulping from pockets of air under the ice.

Amphibians often overwinter under the ice. For example, adult Northern Leopard Frogs (*Lithobates pipiens*) can spend winter months dormant in shallow pits on the pond bottom (Emery et al. 1972. Copeia 1972:123–126), and adult Red-spotted Newts (*Notophthalmus viridescens*) spend their lives in ponds that can freeze over (Berner and Puckett 2010. J. Exp. Zool.

313A:231–239). In these reports, overwintering amphibians are slow or dormant. Our observations indicate high activity levels on larval *A. mavortium* under the ice. This high activity is seen in the other organisms in Swalls Lake. Aquatic arthropods were also seen at high density and high activity. In addition, bubbles were constantly forming and releasing from the surface of cattail stems that were covered with biofilms (presumably algae and cyanobacteria).

Our video recordings are archived at amphibiangrowthproject.org and at youtube.com/user/Kidbeachy. The AGP has been supported by grants from the National Center for Research Resources (5P20RR016471-12) and the National Institute of General Medical Sciences (8 P20 GM103442-12) from the National Institutes of Health to CKB and D. Sens. Long term access to Swalls Lake is kindly provided by the North Central Research Extension Center of North Dakota State University and its director, J. Fisher.

***CRYPTOBRANCHUS ALLEGANIENSIS ALLEGANIENSIS* (Eastern Hellbender). AGGREGATE BEHAVIOR.** *Cryptobranchus alleganiensis* is a large, fully-aquatic salamander that resides beneath boulders and in bedrock crevices in cool, swift flowing streams throughout much of the eastern USA (Nickerson and Mays 1973. The Hellbenders: North American "Giant Salamanders." Milwaukee Public Museum, Milwaukee, Wisconsin. 106 pp.; Smith 1907. Biol. Bull. 13:5–39). Hellbenders are typically described as a solitary and territorial species (Humphries and Pauley 2005. Amer. Midl. Nat. 154[1]:135–142; Nickerson and Mays 1973, *op. cit.*; Smith 1907, *op. cit.*). However, during the breeding season (late summer and fall) sexually mature adults are known to congregate briefly at rock nesting cavities and may aggressively defend rock shelters from conspecifics (Smith 1907, *op. cit.*). Rarely, more than one hellbender has been located beneath a single rock for reasons other than breeding (Hillis and Bellis 1971. J. Herpetol. 5[3-4]:121–126; Nickerson and Mays 1973, *op. cit.*). Nickerson and Mays (1973, *op. cit.*) located three Ozark Hellbenders (*C. a. bishopi*) from beneath a single rock on two occasions, and two individuals from beneath a single rock on 14 occasions in North Fork of the White River, Missouri, USA. Hillis and Bellis (1971, *op. cit.*) found more than one Eastern Hellbender (*C. a. alleganiensis*) under a single rock once during a study in French Creek, Pennsylvania, USA. Because reports of hellbender cohabitation by Nickerson and Mays (1973, *op. cit.*) and Hillis and Bellis (1971, *op. cit.*) resulted from rock-lifting surveys, it remains unclear whether cohabitants beneath a single rock may have been compartmentalized from each other and whether cohabitation may have been a short-term artifact of disturbance caused by survey methods. For example, Hillis and Bellis (1971, *op. cit.*) report that hellbenders being pursued would often crawl beneath a nearby rock sometimes occupied by another hellbender.

On 16 September and 27 October 2012, we observed an aggregation of nine and four hellbenders, using a single bedrock cavity in a stream within the South Fork Holston River drainage (HUC 06010102), Washington Co., Virginia, USA. Due to the current status of *C. alleganiensis* (Fed. Register 2011a. 76[194]:61956–61978; Fed. Register 2011b. 76[194]:61978–61985) and threats of illegal collection we do not report the specific locality of our observations. The site consisted of an approximately 10-m long pool just below a large riffle. Though numerous large rocks occurred upstream of the adjacent riffle and downstream of the pool, suitable shelter for hellbenders within the immediate vicinity largely consisted of bedrock crevices. We used snorkeling gear and dive lights (Underwater Kinetics, Poway, California, USA) to peer into crevices and locate animals. On 16 September 2012 we observed eight hellbenders in a single cavity (85 cm long × 5.4 cm high) at ca. 1700 h (water temperature 17°C; air temperature 19.2°C). The cavity was located along a submerged bedrock face, and was oriented horizontal to but ca. 30 cm below the water surface and 66 cm above a rock ledge that was elevated 109 cm above the stream bed. While photographing the aggregation of hellbenders, we observed a ninth individual approach from upstream apparently intending to enter the cavity. We captured the ninth individual by hand and noted a lack of morphological characteristics indicating sexual maturity (lack of a swollen cloaca or gravid appearance; Makowsky et al. 2010. Herpetol. Conserv. Biol. 5[1]:44–48). Upon release at the location of capture the ninth individual readily entered the cavity without obvious protest from the crevice dwellers. All of the hellbenders we observed were facing the cavity opening and were in physical contact with at least one other individual (http://youtu.be/xl-ErtfB1ug). To rule out the possibility that our observation represented an isolated aberration from normal behavior, we revisited the site on 27 October 2012 at ca. 1300 h (water temperature 14.4°C; air temperature 17.2°C) and observed four individuals using the same cavity (Fig. 1).

FIG. 1. Aggregation of four Eastern Hellbenders (*Cryptobranchus alleganiensis alleganiensis*) on 27 October 2012 in a Virginia, USA, stream.

Though our observations occurred during the breeding season for hellbenders in Virginia (late August–October), we consider it unlikely that the aggregation was an attempt to breed based on the lack of evidence of a nest within the cavity (i.e., no eggs were observed), entrance of an apparently immature individual into the cavity, lack of obvious aggression noted between conspecifics, and observation of the behavior outside a single occasion. Our observations indicate hellbenders may aggregate for reasons other than breeding, though the reason and commonality of such behavior across the range of *C. alleganiensis* is unclear.

C. M. BODINOF JACHOWSKI (e-mail: cjachowski@vt.edu) and **W. A. HOPKINS** (e-mail: hopkinsw@vt.edu), 100 Cheatham Hall, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061, USA.

***SIREN INTERMEDIA* (Lesser Siren). PREDATION.** Confirmed predators of Lesser Sirens include snakes (*Agkistrodon piscivorus, Farancia abacura, Nerodia cyclopion, N. erythrogaster, N. fasciata*), wading birds (*Ardea herodias, Casmerodius albus*), Red-shouldered Hawk (*Buteo lineatus*), Largemouth Bass (*Micropterus salmoides*), and American Mink (*Mustela vison*); Anderson et al. 2006. Herpetol. Rev. 37:233–234; Dobbs and Dobbs 2003. Herpetol. Rev. 34:47; Frese and Britzke 2001. Herpetol. Rev. 32:99; Leja 2005. *In* M. J. Lannoo [ed.], Amphibian Declines: The

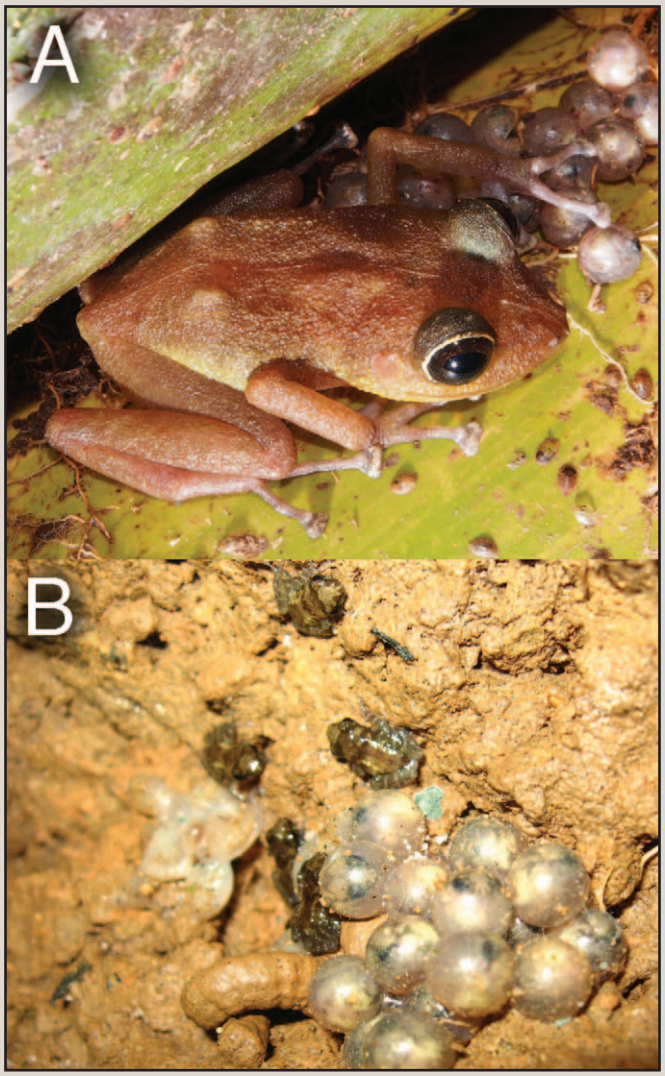
Conservation Status of United States Species, pp. 910–912. Univ. California Press, Berkeley). Herein I provide evidence of Lesser Siren predation by a Coyote (*Canis latrans*).

On 2 March 2012, I found a dead adult male Lesser Siren (277 mm SVL, 394 mm total length) in a shallow (<30 cm), seasonally-inundated pond on Horseshoe Lake State Fish and Wildlife Area HLSFWA), Alexander Co., Illinois, USA. Bite marks and scratches on the siren's head, body, and tail indicate it was killed by a mammal. I compared a complete set of canine-teeth punctures on the siren's body with skulls of carnivorous mammals that occur in southern Illinois. Upper and lower canines of Coyote skulls matched the puncture wounds in the siren.

Although Coyotes feed principally on terrestrial animals (Bekoff 1977. Mammalian Species 79:1–9), they have been observed in water capturing aquatic prey (Grimm 1940. J. Mammal. 21:458–459; Minckley 1965. J. Mammal. 47:137). Coyotes are common on HLSFWA (pers. obs.) and may be attracted to wetlands in late-winter and early spring by chorusing frogs. The Coyote did not eat the Siren. Copious mucous produced by Lesser Sirens (Reno et al. 1972. Copeia 1972:625–631) may be distasteful to Coyotes or may have facilitated the Siren's escape after receiving mortal injuries.

I thank Robert Bluett for funding that made this observation possible, Erin Palmer for the loan of Coyote skulls, and Paul Frese for alerting me to a reference.

JOHN G. PALIS, Palis Environmental Consulting, P.O. Box 387, Jonesboro, Illinois 62952 USA; e-mail: jpalis@yahoo.com.



ANURA — FROGS

***ELEUTHERODACTYLUS COOKI* (Coquí Guajón). NESTING SITE.** *Eleutherodactylus cooki* is a threatened direct-developing frog endemic to southeastern Puerto Rico. *Eleutherodactylus cooki* is considered a habitat specialist that uses caves formed by large granodiorite boulders, crevices, and grottos in rocky streams for reproduction (Joglar 1998. Los Coquíes de Puerto Rico: Su Historia Natural y Conservación. Editorial de la Universidad de Puerto Rico, San Juan. 232 pp.). Males can attend up to four clutches with an average size of 17 eggs per clutch, which are laid on vertical surfaces or in crevices of these plutonic rocks (Burrowes 2000. Herpetologica 56:375–386). Herein we report two new *E. cooki* nesting sites that are not on the typical granodiorite substrate.

On 16 Nov 2012, we found an adult male (40.4 mm SVL; 4.93 g) guarding one egg clutch laid on the surface of a green bamboo trunk (Fig. 1A). The bamboo (*Bambusa vulgaris*) was ca. 2 m away from large granodiorite formations in a small stream in Patillas, Puerto Rico (18.050°N, 65.990°W). The egg clutch contained 16 gray embryos corresponding to developmental stage VI: legs are visible and the white yolk is greatly reduced (Burrowes 2000, *op. cit.*).

On 19 Nov 2012, we found an adult male guarding a double-clutched nest in a muddy substrate located below a large boulder (Fig. 1B). The nesting site was located ca. 1 m away from the stream bank, which is part of a designated U.S. Fish and Wildlife Service critical habitat (Unit 2: Montones in Las Piedras, Puerto Rico; 18.148°N, 65.917°W). We observed five recently hatched juveniles from one of the clutches, and 14 embryos in developmental stage V: pink coloration, frequent rapid movements (Burrowes 2000, *op. cit.*).

Both of these localities were characterized by a high abundance of calling *E. cooki* males. Thus, our observations suggest that when nesting sites on granodiorite surfaces are limited, *E. cooki* can select other substrates to lay and attend egg clutches.

PHOTOS BY (A) ALBERTO L. LÓPEZ-TORRES, AND (B) CARLOS A. RODRÍGUEZ-GÓMEZ

FIG. 1. Photographs taken in the field of A) male *Eleutherodactylus cooki* guarding an egg clutch in a bamboo trunk; and B) double-clutched nest with recently hatched juveniles on the left and 14 well-developed embryos on the right.

ZEGARRA**, USFWS, PO Box 491, Boquerón, Puerto Rico 00622 (e-mail: jan_zegarra@fws.gov).

***LEPTODACTYLUS BUFONIUS* (Oven Frog). PREDATION.** Ants have been documented as predators of juvenile anuran (Clerke and Williamson 1992. Austr. Zool. 28:64–67), and eggs (Dayton and Jung 1999. Herpetol. Rev. 30:164; Schalk 2012. Herpetol. Rev. 43[4]:635). The following observation documents the predation of tadpoles of *L. bufonius* by ants.

On 19 March 2012 at 2100 h, we came upon a pond that had recently dried (< 24 h) in the Yande Yari guard post (18.69181°S, 62.30192°W; WGS 84), Kaa-Iya National Park, Cordillera Province, Santa Cruz Department, Bolivia. On the still-moist mud we observed a total of 28 *Leptodactylus bufonius* tadpoles that were

being attacked by black ants (ca. 10 mm in length; Formicidae). The tadpoles were still alive; as they were attacked they would flick their tails from side to side in an attempt to free themselves from the jaws of the ants. We observed the ants for ca. 20 minutes, during which time two tadpoles were carried off by several ants.

The presence of breeding ponds across the Chacoan landscape is extremely dynamic; ponds can dry down and refill completely multiple times within a rainy season (pers. obs.). Many anurans of the Gran Chaco possess physiological or behavioral adaptations to cope with the xeric conditions of region (Schalk 2012. Herpetol. Rev. 123–124, and references therein). With this observation, it appears that tadpoles of *L. bufonius* can persist outside of the water, at least for short periods of time, but it also exposes them to terrestrial predators they would not otherwise encounter.

Funding for this research was provided by the National Science Foundation's Graduate Research Fellowship Program and the Applied Biodiversity Science NSF-IGERT Program at Texas A&M University (NSF-IGERT Award # 0654377).

Irala 565, Casilla 2489, Santa Cruz de la Sierra, Bolivia (e-mail: marco_23735@hotmail.com); **CHRISTOPHER M. SCHALK,** Department of Wildlife and Fisheries Sciences, Texas A&M University, College Station, Texas 77843-2258, USA (e-mail: cschalk@tamu.edu).

***LEPTODACTYLUS MELANONOTUS* (Sabinal Frog). ENDOPARASITISM.** *Leptodactylus melanonotus* is a small frog ranging from NW Mexico to Central America and Ecuador, in arid and wet mountain woodlands. The species is nocturnal, semiaquatic, insectivorous, oviparous, and can persist in anthropogenically disrupted areas; it is indeed an indicator of impacted areas (Ramírez-Bautista and García 2002. *In* Noguera et al. [eds.], Historia Natural de Chamela, pp. 251–264. Universidad Nacional Autónoma de México). According to IUCN – the World Conservation Union, *Leptodactylus melanonotus* is listed in the category of Least Concern with populations considered as "stable" (Solís et al. 2010. *In* IUCN Red List of Threatened Species. Version 2012.1, www.iucnredlist.org, accessed 28 June 2012).

During recent survey work on metazoan parasites of *L. melanonotus* in the Chamela-Cuixmala Biosphere Reserve in Jalisco, west-central Mexico, 20 specimens of *L. melanonotus* were examined for parasitic mites. One frog (prevalence 5%) was parasitized with 10 chiggers *Hannemania hylae* (Leeuwenhoekiidae) from Chamela Creek (19.52738°N, 105.06994°W). Chiggers were found on the ventral skin, into the subdermal layer of the trunk and thighs of the host. Frogs were collected under permit FAUT-0250 issued to Gerardo Suzán and will be deposited at Colección Herpetológica, Estación de Biología Chamela. Voucher chigger specimens are housed at the Colección Nacional de Ácaros, Universidad Nacional Autónoma de México, Instituto de Biología, México, D.F., with accession numbers CNAC 007098–007102.

This is the first record of *Hannemania hylae* on *Leptodactylus melanonotus*. This chigger ranges from the southwestern USA to Argentina. It has previously been reported to parasitize *Hyla arenicolor, Pseudacris cadaverina,* and *Eleutherodactylus guttilatus* from several localities in the USA (Jung et al. 2001. Herpetol. Rev. 32:33–34; Loomis and Welbourn 1969. Bull. South. California Acad. Sci. 68:160–168). Also, it has been reported from *Pseudacris cadaverina, Lithobates berlandieri, Eleutherodactylus* sp., *Eleutherodactylus longipes, Lithobates* sp., *Scaphiopus couchii,* and *Incilius mazatlanensis* from Mexico (Espino del Castillo et al. 2011. Int. J. Acarol. 37:427–440; Goldberg et al. 2002. Herpetol. Rev. 33:301–302; Hoffmann 1969. Rev. Latinoam. Microbiol. Parasitol. 11:209–216; Hoffmann and López-Campos 2000. Biodiversidad de los Ácaros en México. CONABIO, UNAM, México. 230 pp.; Loomis and Welbourn 1969, *op. cit.*); and also known to infest *Hypsiboas curupi* from Argentina (Alzuet and Mauri 1985 [1987]. Rev. Soc. Entomol. Argentina 44:111–116).

***LEPTODACTYLUS SAVAGEI* (Savage's Thin-toed Frog). PREY.** *Leptodactylus savagei* is a large species distributed in primary and secondary forests, forest edges, and deforested areas from Honduras, Nicaragua, Costa Rica, Panama, and scattered localities in both the Caribbean and Magdalena Valley regions of Colombia, from sea level to 1385 m (Heyer 2005. Arq. Zool. 37:269–348; Heyer et al. 2010. Cat. Amer. Amphib. Reptiles 867:1–19). This species is known to feed on diverse prey types from arthropods to small vertebrates (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. xx + 934 pp). Among vertebrate prey items, *L. savagei* is known to feed on adults of both *Hypsiboas rosenbergi* and *Engystomops pustulosus* (Kluge 1981. Misc. Publ. Mus. Zool., Univ. Michigan 160:1–170; Ryan et al. 1981. Behav. Ecol. Sociobiol. 8:273–278). In Colombia, *L. savagei* and *E. pustulosus* occur sympatrically in the Middle Valley of the Madgalena River. Based on a stomach content analysis, herein we report the predation of *L. savagei* on *E. pustulosus* at an open area in the Reserva Rio Manso (5.666°N, 74.7745°W, WGS84; ca. 220 m elev.), municipality of Norcasia, department of Caldas.

On 12 May 2010 at 1924 h, GGD collected an adult male *L. savagei* (SVL 58.7 cm; MHN-UC 460) on the border of a small pond about 1 m diameter, with a chorus of *E. pustulosus*. The stomach of the *L. savagei* contained two *E. pustulosus*, a mature female (26.8 mm SVL; MHN-UC 461) and other individual (24.7 mm SVL; not sexed due its state of decomposition). To our knowledge, this is the first record in Colombia of *L. savagei* feeding on *E. pustulosus* and the second report through its distribution range. The specimens are housed on Museo de Historia Natural of the Universidad de Caldas (MHN-UC), Manizales, Colombia.

We suggest that predation of *E. pustulosus* by *L. savagei* could be an opportunistic event or by convenience, because anurans that predate other anurans are not predators specialized on anurans, but feed on them with regularity (Toledo et al. 2007. J. Zool. 271:170–177). Because *L. savagei* often breeds near sites of activity of *E. pustulosus* (Ryan et al. 1981, *op. cit.*), the syntopic occurrence of these two species during reproductive aggregations can promote the predation of the latter species by an opportunistic predator like *L. savagei*.

We are grateful to A. M. Jaramillo for providing logistic help in the Reserva Privada Riomanso. PDAGC received Ph.D. grants from CAPES (bolsista da CAPES/CNPq – IEL Nacional - Brasil).

***LITHOBATES BERLANDIERI* (Rio Grande Leopard Frog). LEARNED FEEDING BEHAVIOR AND DIET.** Primarily nocturnal, seeking shelter in thick vegetation and under rocks during the day, *Lithobates berlandieri* is generally found in clear flowing streams or permanent pools that originate from springs (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.). The species is a generalist, opportunistic predator whose diet is most strongly influenced by prey availability (Parker and Goldstein 2004. J. Herpetol. 38:127–130) and includes a variety of insects and invertebrates (Degenhardt et al. 1996, *op. cit.*). Herein we document a learned feeding behavior of *L. berlandieri* for a temporally specific prey, the honeybee.

On the night of 27–28 June 2005, we were netting bats over the pool at La Cienaga, a natural spring in the western quarter of the Chinati Mountains State Natural Area (CMSNA), Presidio Co., Texas, USA. Situated in typical Chihuahuan Desert, La Cienaga is a natural seep spring with a marshy drainage of dense grasses dominated by Saltgrass (*Distichlis spicata*) and Alkalai Sacaton (*Sporobolus airoides*), the interior of the cienaga is covered by cattail (*Typha latifolia*) and bulrush (*Scirpus* sp.) (Jones et al. 2011. Occas. Pap. Mus. Texas Tech Univ. No. 300, 29 pp.). Before CMSNA was founded, ranch owners built a circular stone and concrete pool for human bathing with the cold water flowing into the pool under spring pressure. The ca. 1.27 m high pool has six steps, each ca. 21 cm high, rising to a ca. 1 m wide concrete rim. Between first light and sunrise on 28 June, we observed two large *L. berlandieri* jump each of the six concrete steps and into the pool water, the first did so while SK was sitting on the steps, determined to reach the water. We did not disturb their progress. Just after sunrise, hundreds of honeybees, *Apis mellifera* (Hymenoptera: Apidae), swarmed over the water and began to dip and short-rest on the water's surface. Desert honeybees must collect water for thinning of honey to feed larva and evaporative cooling of the hive (Nicolson 2009. J. Exp. Biol. 212:429–434). The two *L. berlandieri* swam underwater towards the resting honeybees and each took one honeybee, swam down into the dark detritus material at the bottom of the pool, and then intermittently returned to the surface. These leopard frogs continued to take honeybees using this method until the swarm of honeybees nearly dissipated. We estimated that 6–8 honeybees were taken by the two *L. berlandieri* during ca. 4–5 min of observations. Although not directly observed, the *L. berlandieri* were either consuming each bee while near the bottom or were inserting the captured bees into the detritus layer. If the latter is correct, this feeding behavior could be a strategy for food hoarding and time management of a temporally restricted resource, and a practice to neutralize a dangerous prey.

In a comparison study of five populations of *L. berlandieri* from Texas, the population from Big Bend National Park in Brewster Co., Texas (the nearest locality to CMSNA), had the least diverse spring diet, almost evenly distributed among Lepidoptera (33%), Coleoptera (27%), and Hymenoptera (33%), however only one prey item was identified to the family Apidae from 27 spring frogs sampled across three localities, including Big Bend (Parker and Goldstein 2004, *op. cit.*). Hymenoptera were listed in the diet of two species of eastern Texas leopard frogs, *L. clamitans* (10.7%) and *L. sphenocephala* (7.1%), although no discrimination was made to bee, ant, or wasp (Forester et al. 1998. Herpetol. Rev. 29:208–211). Examination of 31 *Rana aurora* indicated that each of three frogs had a single honeybee in their diet (Hayes and Tennant 1985. Southwest. Nat. 30:601–605). The limited number of prey items identified to Apidae in these studies infers that bees are not a regular component in the diet of *Lithobates* or *Rana*.

Generally, leopard frogs appear to recognize potential prey by continuous movement that elicits a predatory response (Hayes and Tennant 1985, *op. cit.*), choosing prey from any moving object that is of an appropriate size (Forester et al. 1998, *op. cit.*). Although some frogs may develop preferences, dietary studies of ranid frogs as a group tend to reflect habitat and prey availability (Forester et al. 1998, *op. cit.*). We found that these two *L. berlandieri* developed a prey preference defined on a temporal component. It appears that these honeybees came to water around sunrise on a regular basis with the leopard frogs seemingly needing to make a time appointment for prey, as evidenced by being undeterred by our direct presence. The water may be too cold to spend extended periods in the pool at night, and these two *L. berlandieri* learned a strategy to take a regular prey based on a sunrise schedule. Two subsequent visits to net bats at the site on 21 June 2007 and 9 July 2008 indicated the presence of *L. berlandieri* in the grasses at La Cienaga, however no leopard frogs or honeybees were observed in the pool around sunrise, possibly due to an extirpated prey source.

***LITHOBATES CLAMITANS MELANOTUS* (Green Frog). UNUSUAL FOOD ITEM.** Much is known about the food habits and feeding behavior of *Lithobates clamitans* (Pauley and Lannoo 2005. *In* M. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 549–552. Univ. California Press, Berkeley, California). This frog is an opportunistic "sit-and-wait" predator that will feed on various invertebrates and vertebrates during both day and night (Hamilton 1948. Copeia 1948:203–207; Minton 2001. Amphibians and Reptiles of Indiana, 2nd ed. Indiana Academy of Science, Indianapolis, Indiana. 404 pp.). A summary of food items of *L. clamitans* was provided by Hamilton (1948, *op. cit.*), Whitaker (1961. Herpetologica 17:173–179), Stewart and Sandison (1972. J. Herpetol. 6:241–244), and Forstner et al. (1998. Herpetol. Rev. 29:208–211). Herein, we report an unusual food item of *L. clamitans melanotus* from the Ouachita Mountains of Arkansas.

On 25 July 2012, five juvenile Green Frogs (mean ± 1SD SVL 39.8 ± 3.3, range 37–45 mm) were collected from 5.0 km N Mena, off St. Hwy. 88 at Blue Haze Vista Pond, Polk Co., Arkansas, USA (34.62605°N, 94.24444°W; WGS84). Specimens were placed in individual plastic bags on ice and transported to the laboratory within 48 h for necropsy. Frogs were anesthesized with a concentrated chloretone solution and an incision was made to expose the stomach contents. Contents were placed in a Petri dish, rinsed with 0.6% saline, and identified under a stereomicroscope

FIG. 1. Walkingsticks removed from stomachs of Green Frogs, *Lithobates clamitans melanotus* from Arkansas.

using Triplehorn and Johnson (2005. Borrer and Delong's Introduction to the Study of Insects, 7th ed. Thomson/Brooks Cole, Belmont, California. 864 pp.). Voucher specimens of *L. c. melanotus* are deposited in the Arkansas State University Museum of Zoology Herpetological Collection (ASUMZ) as ASUMZ 32392–32396.

Two *L. c. melanotus* (41 and 45 mm SVL) were each found to contain a single adult walkingstick (Phasmatodea: Heteronemiidae) belonging to the genus *Diapheromera* in its stomach (Fig. 1). These insects appear to be unusual food items of *L. clamitans*. Other insects reported as prey of *L. clamitans* includes coleopterans, dipterans, ephermeropterans, hemipterans, lepidopterans, odonates, orthopterans, and trichopterans (Pauley and Lannoo 2005, *op. cit.*). Walkingsticks are slow-moving and the best time to observe them is midsummer to late fall (Triplehorn and Johnson 2005, *op. cit.*). This is the first time, to our knowledge, that walkingsticks have been reported as prey items of *L. clamitans*.

We thank S. E. Trauth (ASUMZ) for expert curatorial assistance, and the Arkansas Game and Fish Commission and USDA Forest Service (Ouachita District) for Scientific Collecting Permits issued to CTM.

***LITHOBATES PIPIENS* (Northern Leopard Frog). MALFORMATION.** On 13 September 2011, AR collected a single metamorphosed *Lithobates pipiens*, 37.8 mm SVL, from a farm field in Minot, Ward Co., North Dakota, USA (48.1044°N, 101.1643°W). This frog contained two supernumerary arms that emerged from the throat (Fig. 1A). Upon collection, AR kept the frog in a plastic container and successfully fed several crickets to the frog. These arms were fully formed, and responded to stimuli (i.e., they would move when pinched with forceps). This frog was capable of full locomotion (i.e., walking, hopping, and jumping). The frog was brought to the Amphibian Growth Project (AGP) and euthanized by prolonged immersion in a 10% solution of MS-222, preserved in 10% formalin, and stored in 70% ethanol. The

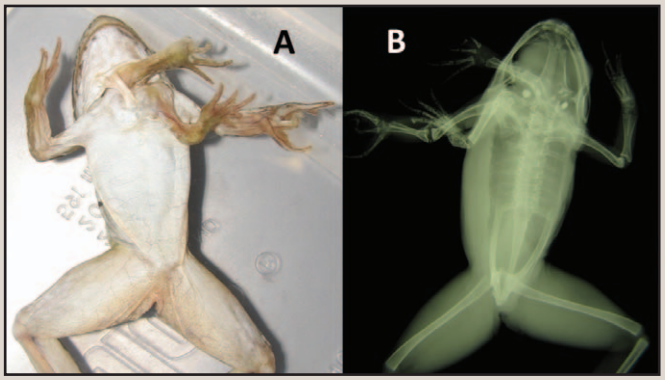

FIG. 1. A) Ventral view of preserved *Lithobates pipiens* collected in Ward Co., North Dakota with two supernumerary arms. B) Radiograph of same individual.

frog was shipped to ML who prepared radiograph images that revealed that these supernumerary limbs contained usual skeletal elements distal to the pectoral girdle (i.e., humerus, radius, ulna, metacarpals, carpels, phalanges). These arms were not articulated to any other part of the skeleton (Fig. 1B).

The AGP maintains a database of life history data for local amphibians that includes over 1250 capture records of *L. pipiens* from 2005–2012 from several sites in northwestern and north central North Dakota. This is the first report of a malformed frog that we are aware of in this region. Metamorphosis in this region occurs during July at ca. 25 mm SVL. Given the timing of collection, the size of the frog, and the observation that this frog could capture and consume prey successfully, we are comfortable with suggesting that this frog was at least 16 months old.

The most likely wetland that produced this frog is ca. 500 m away from the collection site. This wetland is surrounded by farm fields maintained by the North Central Research Extension Office of North Dakota State University. The wetland is generally oval in shape and is approximately 200 x 100 m. It has held water continuously since 2007, but would dry periodically prior to this. When full of water, the maximal depth in this wetland is 1.75 m.

The AGP has been supported by grants from the National Center for Research Resources (5P20RR016471-12) and the National Institute of General Medical Sciences (8 P20 GM103442-12) from the National Institutes of Health to CKB and D. Sens, and from the North Dakota Department of Game and Fish to K. Cabarle and CKB. AR has been a participant in the "Kids in Research" program of the AGP.

BEACHY**, Amphibian Growth Project and Dept. Biology, Minot State University, Minot, North Dakota 58707, USA (e-mail: christopher.beachy@minotstateu.edu).

***LITHOBATES SYLVATICUS* (Wood Frog). DAVIAN BEHAVIOR.** A breeding population of Spotted Salamanders (*Ambystoma maculatum*) has been monitored annually at Bat Lake, Algonquin Provincial Park, Ontario, Canada (45.5857°N, 78.5185°W) as part of an ongoing mark-recapture study. Minnow traps are deployed around the lake perimeter following spring thaw to capture adult *A. maculatum* during the breeding period. Traps are deployed at night and checked the following morning. On 2 May 2009 while checking traps we observed a male *Lithobates sylvaticus* in pectoral amplexus with a gravid female *A. maculatum* (86.0 mm

FIG. 1. Wood Frog (*Lithobates sylvaticus*) in amplexus with a gravid female Spotted Salamander (*Ambystoma maculatum*), Bat Lake, Algonquin Provincial Park, Ontario, Canada.

SVL, 20.5 g mass) (Fig. 1). Both individuals were found inside a submerged minnow trap ca. 1 m below the surface. The frog was tightly clasped around the pectoral girdle of the salamander, immediately posterior to the forelimbs. After photographing, the pair was separated. The *L. sylvaticus* was released without measurement and the *A. maculatum* was measured, weighed, and marked prior to release.

Interspecific amplexus is functionally equivalent to other well characterized Davian behaviors which include misdirected mating with conspecifics, necrogamy, or amplexus with inanimate objects. Observations of interspecific amplexus between anurans are recorded with some regularity (Meshaka 1996. Florida Scient. 59[2]:74–75; Eaton et al. 1999. Can. Field Nat. 113:512–513; Pearl et al. 2005. Am. Mid. Nat. 154:126–134; D'Amore et al. 2009. Herpetol. Cons. Biol. 4:325–330). By contrast, reports of interspecific pairings of salamanders are rare and restricted to specific species or well-characterized hybridization events (Verrell 1990. J. Zool. Lond. 221:441–451; Verrell 1994. Evolution 48:921–925). An exhaustive search of the formal literature revealed few observations of amplexus between an anuran and caudate, including *Bufo bufo* and *Salamandra salamandra* (Marco and Lizana 2002. Ethol. Ecol. Evol. 14:1–8), although this phenomenon is likely underreported.

It has been proposed that Davian behaviors may result from the highly competitive nature of anuran reproduction characterized by seasonal (time sensitive) and explosive reproductive aggregations (Meshaka 1996, *op. cit.*; Reading 1984. J. Zool. Lond. 203:95–101). Given the shared breeding habitat and synchronized breeding periods of *L. sylvaticus* and *A. maculatum*, mate misidentification seems a likely cause. While close confinement may have facilitated the Davian behavior reported here, previous observations of interspecific amplexus in other species affirm that this behavior is naturally occurring. The fact that the frog exhibited a pectoral girdle clasp further suggests that it was attempting to engage in normal amplexus rather than an accidental or temporary effort.

Financial support provided by the Friends of Algonquin Park. Much thanks for in-kind support owing to the Algonquin Wildlife Research Station, Rory Eckenswiller, and Brad Steinberg.

***LITORIA RANIFORMIS* (Growling Grass Frog). LEUCISM.** *Litoria raniformis* is a large, semi-aquatic frog that occurs naturally across south-eastern Australia, including parts of New South Wales, Victoria, Tasmania, and South Australia (Pyke 2002. Austr. Zool. 32:32–48). Introduced populations also occur in New Zealand (Voros et al. 2008 Austral. Ecol. 33:623–629). *Litoria raniformis* is listed as endangered by the IUCN. On 24 January 2012, we caught a leucistic *L. raniformis* in a wetland in Bundoora, Melbourne, Victoria, Australia (37.7°S, 145.033°E). It was found in good physical condition, floating among emergent vegetation near the water's edge. Two adult female *L. raniformis*, of typical green and brown coloration were also caught in the same water body. The leucistic individual was an adult male (64 mm SVL) in breeding condition (Fig. 1). It was entirely yellow with a pink tinge, except for darkly pigmented eyes, and raised brown nuptial pads on its thumbs. The dorsal skin was translucent. We observed the leucistic *L. raniformis* on 22 February 2012 in the same wetland, ca. 30 m from the original point of capture. No attempt was made to recapture this individual. It has been suggested that incidences of leucism and albinism may occur with more frequency in nocturnal or cryptozoic animals, due to selection against these traits in diurnal species with visually orientated predators (Sazima and Di-Bernado 1991. Mem. Inst. Butantan 53:167–173). Interestingly, *L. raniformis* is partly diurnal, with individuals often observed basking in either direct or filtered sunlight (Heard et al. 2006. Wildl. Res. 33:557–564). To our knowledge, this is the first documented case of leucism in *L. raniformis*. A section of toe-web was deposited in the tissue collection of Museum Victoria, Australia (NMVZ 17602).

We thank Geoffrey W. Heard for comments on this note. Our work was funded by an Australian Research Council Linkage Grant (LP0990161) with the Australian Research Centre for Urban Ecology, Growling Grass Frog Trust Fund, Melbourne Museum, Melbourne Water, Parks Victoria, and Victorian Department of Sustainability and Environment.

***OOPHAGA PUMILIO* (Strawberry Poison Frog). PREDATION.** Bright coloration in dendrobatid frogs is presumed to function as an aposematic signal to natural predators with color vision (Saporito et al. 2007. Copeia 2007:1006–1011), thereby warning predators such as birds of the frog's alkaloid-based chemical defenses. The known natural predators of dendrobatid frogs are based largely on anecdotal reports, and include an amphibian, ant, fish, spiders, and snakes (Santos and Cannatella 2011. Proc. Nat. Acad. Sci. 108:6175–6180). *Dendrobates auratus* was reportedly preyed upon by an adult *Baryphthengus martii* (Rufous Motmot) at the La Suerte Biological Station in northeastern Costa Rica (Limon Province), representing the only known bird predator of dendrobatid frogs (Master 1998. Herpetol. Rev. 29:164–165). Herein, we report an additional observation of predation by a Rufous Motmot on *Oophaga pumilio*.

Oophaga pumilio ranges from southern Nicaragua to western Panama (Guyer and Donnelly 2005. Amphibians and Reptiles of La Selva, Costa Rica, and the Caribbean Slope. Univ. California Press, Berkeley. 299 pp.), and falls well within the geographic range of *B. martii* (Garrigues and Dean 2007. *In* The Birds of Costa Rica, p. 146). On 15 May 2011, at the OTS La Selva Biological Station in northeastern Costa Rica (Heredia Province), between 1000–1100 h, we observed two independent events in which one individual of a pair of adult *B. martii* landed on a branch carrying an adult *O. pumilio* in their beak (Sendero Tres Rios trail between 100–150 m; Fig. 1). The pair of Rufous Motmots was observed carrying the captured *O. pumilio* to their nest of chicks only a few meters away, presumably feeding the frogs to their young. Motmots typically nest in deep cavities, and therefore we were not able to observe the chicks feed on the frogs; however, the pair of Rufous Motmots was also observed bringing to its nest spiders and fruits of *Virola koschnyi* (Myristicaceae). Rufous Motmots are reported to feed on the fruits of palms and members of the plant genus *Heliconia*, as well as insects, spiders, small frogs, lizards, fishes, and crabs (Stiles and Skutch 1989. *In* A Guide to the Birds of Costa Rica, p. 242). To the best of our knowledge, this represents only the second report of a Rufous Motmot feeding upon a dendrobatid, and the first report of these birds feeding their young a dendrobatid poison frog. Further research is needed to determine the extent to which *O. pumilio* is preyed upon by *B. martii*, the importance of *O. pumilio* as a dietary source for developing chicks, and how *B. martii* are presumably immune to the alkaloid defenses of *O. pumilio*.

FIG. 1. An adult *Oophaga pumilio* (Strawberry Poison Frog) being preyed upon by an adult *Baryphthengus martii* (Rufous Motmot) at La Selva Biological Station, Costa Rica during May 2011.

JOEL B. ALVARADO and **ALEX ALVAREZ**, Organization for Tropical Studies, La Selva Biological Station, Costa Rica; **RALPH A. SAPORITO**, Department of Biology, John Carroll University, University Heights, Ohio 44118, USA (e-mail: rsaporito@jcu.edu).

***PELOPHRYNE MISERA* (Kinabalu Dwarf Toad). NOVEL MICROHABITAT AND MAXIMUM SIZE.** *Pelophryne misera* is a minute anuran (to 21 mm SVL in males, and 23 mm SVL in females) (Inger and Stuebing 2005. A Field Guide to the Frogs of Borneo. 2nd ed. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. viii + 201 pp.) which is endemic to Borneo (Mount Kinabalu in Sabah and Mount Murud in Sarawak of Malaysia, and Upper Sulon in East Kalimantan of Indonesia) (Malkmus et al. 2002. Amphibians and Reptiles of Mount Kinabalu [North Borneo]. A.R.G. Gantner Verlag K.G. Ruggell. 424 pp.; Veith et al. 2004. Tropical Zool. 17:1–13; Inger and Stuebing 2005, *op. cit.*). The species inhabits primary and old secondary mossy forests on the forest floor (breeding site) and sometimes in low vegetation 10–50 cm from the ground at 1450–3140 m elev. (Malkmus et al. 2002, *op. cit.*). The species is listed as Vulnerable in 2011 IUCN Red List of Threatened Species primarily due to restricted distribution, but is deemed locally abundant (Inger et al. 2004. *In* IUCN 2011. IUCN Red List of Threatened Species. Version 2011.2. <www.iucnredlist.org>. Accessed on 15 June 2012). There is still inadequacy in the natural history understanding on *P. misera* attributed to the scarcity of its record of occurrence, and thus, herein we report a novel microhabitat at an extended vertical dimension, and maximum size for *P. misera*.

On 11 December 2008, between 1900 and 2200 h, three *P. misera* were discovered via opportunistic examination at Geludu Trail (6°N, 116.5375°E; 1478 m elev.) on Geludu Hill, Bundu Tuhan, Ranau District, West Coast Division, Sabah, Bornean Malaysia. Air temperature was 17.3°C, and relative humidity was 86%. The individuals were located among mosses covering a part of an old iron water pipe at 150 cm above the ground. Approximately 25 m of the 30-cm-diameter pipe was exposed from the ground caused by erosion that happened quite some time ago as indicated by surrounding thick leaf litter and compacted soil, while the rest of the pipe was still buried underground. The three *P. misera* were found close to one another about 5 m from a buried edge of the pipe. The pipe is utilized to supply clean water to nearby villages.

Intensive search did not find potential predators in proximity. The finding of three individuals, coupled with the absence of predators omit the causal factors of randomness and predator avoidance for the occurrence of *P. misera* at the novel microhabitat. Moisture might have played a role in motivating *P. misera* to occupy the long patch of live mosses on the exposed water pipe as moisture is an imperative factor determining the selection of non-breeding microhabitats for anurans for foraging, thermoregulation, and dispersal (Blomquist and Hunter 2009. Herpetol. Conserv. Biol. 4[2]:142–160). Documentation and understanding of non-breeding microhabitats are equally as crucial as of breeding sites and tadpole habitats in the conservation of anurans (Gillespie et al. 2004. J. Trop. Ecol. 20:439–448; Regosin et al. 2005. J. Wildl. Mgmt. 69[4]:1481–1493), particularly of non-stream breeding species such as *P. misera*.

The three adult *P. misera* were determined to be two females (27 mm SVL, mass 0.4 g and 27 mm SVL, mass 0.3 g) and one male (16 mm SVL, mass 0.3 g) based on the presence of a row of yellowish brown mandibular spines on the male (Malkmus et al. 2002, *op. cit.*), and adult SVL ranges (Inger and Stuebing 2005, *op.*

cit.). SVL and weight were measured with a standard metric tape and an electronic balance. The individuals were photographed *ex-situ* indoors, and euthanized under the permission granted by the pertinent authority. The voucher specimens (Female 1: HEP00916; Female 2: HEP00917; Male 1: HEP00915) were deposited in BORNEENSIS, the Bornean reference collection of the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah. The two females represent the new maximum SVL for *P. misera*.

We are grateful to Indraneil Das (Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak) for verification of the species. We thank Agnes James Lintanga for field assistance, Paulus Abas for field transportation, and Haleluyah Retreat Centre for lodgings support. Sampling was conducted under the permission granted by the Jawatankuasa Pemegang Amanah Hutan Simpanan dan Tanah Perumahan Bumiputera Kg. Bundu Tuhan, Ranau, to KBH. We also thank the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah for support.

***PHYSALAEMUS GRACILIS* (Graceful Dwarf Frog). DEFENSIVE BEHAVIOR.** Many animal lineages independently developed different defensive behaviors in response to the presence of visually oriented predators (Bertoluci et al. 2007. Alytes. 25:38–44). Among anurans, defensive behaviors are divided into 30 categories (Toledo et al. 2011. Ethol. Ecol. Evol. 23:1–25), among them, the stiff-legged behavior (Sazima 1978. Biotropica 10:158). In this type of behavior the animal is motionless, with body flattened and legs stretched out (Costa et al. 2009. Herpetol. Notes 2:227–229). This behavior has been little reported anurans, comprising less than 5% of observations (Toledo et al. 2011, *op. cit.*). However, the behavior has been reported in Bufonidae (*Dendrophryniscus leucomystax, D. brevipollicatus, D. berthalutzae*), Brachycephalidae (*Euparkerella cochranae),* Cycloramphidae (*Proceratophrys boiei, P. appendiculata, P. melanopogon, Zachaenus parvulus*), Leptodactylidae (*Paratelmatobius poecilogaster, Scythrophrys sawayae*) and Microhylidae (*Arcovomer passarellii, Ctenophryne geayi, Stereocyclops parkeri, S. incrassatus*) (Toledo et al. 2011, *op. cit.*; Tonini et al. 2011. Herpetol. Notes 4:435–444). *Physalaemus gracilis* is possibly a complex of more than one species (IUCN 2012. IUCN Red List of Threatened Species. http://www.iucnredlist.org/amazing-species). It dwells in forest borders and Cerrado grasslands in Brazil, Paraguay, Uruguay, and Argentina, and is strongly adapted to disturbed and polluted environments (Frost 2011. http://research.amnh.org/vz/herpetology/amphibia/; IUCN 2012. IUCN Red List of Threatened Species. http://www.iucnredlist.org/amazing-species). On 11 Jan 2010 at 2000 h., we observed defensive behavior by a *P. gracilis* upon capture. After being manually captured and released moments after on the ground, the frog remained still with its legs stretched during more than 3 minutes (Fig. 1). The observation occurred in a temporary pool in an urban street in the town of Xangri-lá, north coast of the state of Rio Grande do Sul, Brazil (29.4712°S, 50.0143°W). Although other kinds of defensive behaviors have been observed in the Leiuperidae (Toledo et al. 2010. J. Nat. Hist. 44:1979–1988), our report is the first case of the stiff-legged defensive behavior for this family.

FIG. 1. *Physalemus gracilis* from Rio Grande do Sul, Brazil displaying the stiff-legged defensive behavior.

SABINE BORGES DA ROCHA (e-mail: sabineborges@hotmail.com) and **FERNANDO IBANEZ MARTINS**, Universidade Federal de Mato Grosso do Sul, Programa de Pós-graduação em Biologia Animal, 79070-900, Campo Grande, MS, Brazil.

***RHINELLA SCHNEIDERI* (Rococo Toad). BREEDING SITE.** *Rhinella schneideri* is a giant toad (210 mm maximum SVL) occurring in the xeric regions of Bolivia, Argentina, Paraguay, and Brazil (Cei 1980. Zool. Ital. Monogr. 2:1–609). Relatively little information is available on its breeding site associations. In soybean farmlands in Argentina, *R. schneideri* was found to occur around larger ponds that contained high diversity of vegetation along the pond's shore (Peltzer et al. 2006. Biodiv. Cons. 15:3499–3513). The association with vegetative structure is likely the result of its reproductive mode; it deposits its eggs in long gelatinous strings that are attached to aquatic plants (Cei 1980, *op. cit.;* Perotti 1997. Rev. Chil. His. Nat. 70:277–288). Observations on the reproductive biology of this species in other parts of its range are lacking. Here we describe a breeding site of *R. schneideri* in the Bolivian Gran Chaco.

While crossing the Parapetí River on 29 January 2011, we heard a chorus of three *R. schneideri* calling from a temporary pond located within the riverbed outside the community of Rancho Viejo, Cordillera Province, Santa Cruz Department, Bolivia (19.44055°S, 62.53694°W; WGS 84). This pond had most likely been formed by the floodwaters of the river, which had receded when we had crossed it. The next day we returned to the pond which was ca. 200 m from the nearest forest cover, and observed hundreds of *R. schneideri* tadpoles swimming within the pond. We did not observe any recently oviposited egg strands. The pond, which lacked both vegetative and woody debris structure, was ca. 13 m long, and 5 m wide with a substrate comprised entirely of sand. We also observed larval odonates (Corduliidae) within the pond.

The breeding site used is not consistent with previous reports documenting *R. schneideri*'s high affinity for breeding ponds with high aquatic and shoreline vegetation, as any sort of habitat structure was absent in this pond. While habitat structure was lacking, the pond's isolation may provide an amenable environment for the tadpoles of *R. schneideri*; the predator abundance and diversity was reduced as compared to other temporary ponds in the

region (Schalk, unpubl. data) and there were no other species of tadpoles co-occurring in the pond. Body size is generally positively correlated with vagility in amphibians (Duellman and Trueb 1986. Biology of Amphibians. McGraw Hill, New York. 610 pp.), thus the larger bodied *R. schneideri* may be able to make the long forays to these riverbed pools allowing them to exploit these ponds.

CMS was supported by the National Science Foundation's Graduate Research Fellowship Program and the Applied Biodiversity Science NSF-IGERT Program at Texas A&M University (NSF-IGERT Award # 0654377).

***SCINAX FUSCOVARIUS* (Snouted Treefrog). PREDATION.** Vertebrates, invertebrates, and carnivorous plants are commonly documented as predators of anuran eggs, tadpoles, and post-metamorphic individuals (Toledo 2005. Herpetol. Rev. 36[4]:395–400). Most predation records by invertebrates upon anurans are credited to representatives of four classes of Arthropoda: Arachnida, Insecta, Crustacea, and Chilopoda (McCormick and Polis 1982. Biol. Rev. 57[1]:29–58). In the Neotropical region, spider predation upon frogs is mainly attributed to five spider families (Ctenidae, Pisauridae, Lycosidae, Sparassidae, and Theraphosidae; Menin at al. 2005. Phyllomedusa 4[1]:39–47), with the genera Ctenus, Cupiennius, and Oligoctenus (all ctenids) the three most typically documented (reviews in Menin et al. 2005, op. cit.; Toledo 2005, op. cit.). By the year 2009, the genus Phoneutria, including the medically important Brazilian ctenid Phoneutria nigriventer (Eickstedt 1994. In B. Barravieira [ed.], Venenos Animais: uma Visão Integrada, pp.151–172. EPUC, Rio de Janeiro), had not yet been recorded in the literature as an invertebrate predator of frogs (Santana et al. 2009. Bol. Mus. Biol. Mello Leitão 26:5965).

Herein, I report the spider *P. nigriventer* preying upon *Scinax fuscovarius*. During a herpetofaunal survey conducted on 30 May 2010 in a riparian forest near the Mogi-Mirim River (municipality of Conchal, state of São Paulo, southeast Brazil), I observed an adult *P. nigriventer* (31.2 mm cephalothorax + abdomen length) capturing an adult *S. fuscovarius* (26.1 mm SVL) on a road (disturbed sandy soil, with some holes and roots mixed with the ground, for maintenance of a small dirt road), following the edge of the riparian forest 10–15 m distant from the river margin. I observed the scenario just when the spider inserted its chelicerae into the frog's body along the side. The frog attempted to escape but became paralyzed a few minutes later. The predation (Fig. 1) was observed at night (2005 h), during peak activity of both species, in secondary Atlantic Forest (22.273822°S, 47.1866472°W; 579 m elev.). The weather was windy and cloudy; air temperature was 19.2°C; humidity 85.8%. I also observed ca. 30 *S. fuscovarius*, randomly distributed around and near the predation site, although none were heard calling. Approximately 15 *P. nigriventer* were also observed. I observed this event until the moment the spider started to handle the freshly dead frog and to walk in direction to a nearly hole/crevice in the soil, probably its shelter. To ensure vouchers, I then captured both individuals: *S. fuscovarius* was deposited at Coleção de Anfíbios "Célio F. B. Haddad" at UNESP, Rio Claro, Brazil - CFBH 32635, and the spider had been deposited at Butantan Institute, Brazil, but was unfortunately lost in an accidental fire in July 2010. Although this is the first predation record by *P. nigriventer* upon *S. fuscovarius*, considering the nocturnal habits and relatively high local densities for both species, the encounter and predation between these species is likely frequent.

I thank A. Brescovit for identification of the spider and Victor G. Dill Orrico for suggestions on the manuscript. Conselho Nacional de Pesquisa e Desenvolvimento (CNPq) and Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) provided financial support. A collecting permit was issued by IBAMA (process number 02027.003149/2009-14).

FIG. 1. *Scinax fuscovarius* being preyed upon by the spider *Phoneutria nigriventer* (Aranae: Ctenidae).

***SCINAX SQUALIROSTRIS* (Striped Snouted Treefrog). PREDATION.** Predation is an important cause of amphibian mortality, and many cases of predation by spiders are found in the literature (Menin et al. 2005. Phyllomedusa 4[1]:39–47). The neotropical hylid frog *Scinax squalirostris* occurs from central and southeastern Brazil to northeastern Argentina, including Uruguay and southeastern Paraguay. Herein, we report the predation on this species by a spider. On 22 June 2006, at 2130 h, in the Municipality of Vacaria, State of Rio Grande do Sul, Brazil, a *Phoneutria nigriventer* (Ctenidae) was observed preying on an adult male *Scinax squalirostris* (24 mm SVL) on a 40-cm leaf of *Paspalum exaltatum* (Poaceae) at a permanent pond. The spider (cephalotorax 11.2 mm x 8.3 mm) held the hylid with the chelicerae penetrated into its head, but released it when disturbed. The *P. nigriventer* is deposited in the spider collection of Museu de Ciências Naturais, Fundação Zoobotânica do Rio Grande do Sul (MCN 42600), and the *S. squalirostris* is deposited in the herpetological collection of Departamento de Zoologia, Universidade Federal do Rio Grande do Sul (UFRGS 5676).

Bento Gonçalves 9500, prédio 43435, sala 102, Porto Alegre, Rio Grande do Sul, Brazil, CEP 91501-970.

***SCINAX SQUALIROSTRIS* (Striped Snouted Treefrog), *SCINAX AROMOTHYELLA*. MORBID EMBRACE.** The neotropical hylid *Scinax squalirostris* occurs from central and southeastern Brazil

to northeastern Argentina, including Uruguay and southeastern Paraguay. *Scinax aromothyella* occurs in northeast Argentina, Uruguay, and southern Brazil. Herein, we report the occurrence of a morbid embrace at a permanent pond in the Municipality of Vacaria, State of Rio Grande do Sul, Brazil, on 22 June 2006, at 2140 h. An adult male *S. squalirostris* was found being preyed upon by a spider. When disturbed, the spider released the dead treefrog that fell to the ground. However, a few moments later another male *S. squalirostris* vocalizing in the area immediately amplected the corpse. On the same night, in the same pond, other cases of morbid embrace were observed among *S. aromothyella* individuals. Five males were found embracing other recently-dead conspecifics (possibly accidentally killed by researchers trampling). At least two of all corpses found were males. The collected individuals were deposited in the herpetological collection of Departamento de Zoologia, Universidade Federal do Rio Grande do Sul (UFRGS 5675, 5678). These observations occurred on the first rainy night after a long dry spell in that area. We suspect that the animals were under intense reproductive pressure and, due to the desperate attempt at mating, they invested in dead partners and/or those of the same gender.

Bento Gonçalves 9500, prédio 43435, sala 102, Porto Alegre, Rio Grande do Sul, Brazil, CEP 91501-970.

***SCUTIGER BOULENGERI* (Xizang Alpine Toad). NESTING.** While the development of *S. boulengeri* larvae has been previously reported (Song and Huang 1990. Acta Zootaxonomica Sinica 187–193), their nesting behavior is not yet described. From 9–30 June 2012, we observed more than 30 nests across the Qinghai Province of China. Gelatinous eggs were attached as a circular or globular mass to the bottoms of stones in small streams, along the edges of larger streams, and in ephemeral pools (Figs. 1, 2). One average-sized nest was counted and found to contain 323 eggs; some rocks contained multiple nests. Almost all nests were guarded by males, and of the few without male attendance, most appeared to be in various states of decay. Only one female was found underneath a stone with a nest, but a male was also present with the recently laid eggs. In areas where nests occurred, observed males—both with and without nests—outnumbered females more than twenty to one. These observations are consistent with the nest site selection, clutch size, and paternal guarding of nests described for another member of Megophryidae, *Leptobrachium boringii* (Zheng et al. 2011. Asian Herpetol. Res. 2[4]:199–215).

FIG. 1. Overturned *Scutiger boulengeri* nest, guarded by a male, in Qinghai, China.

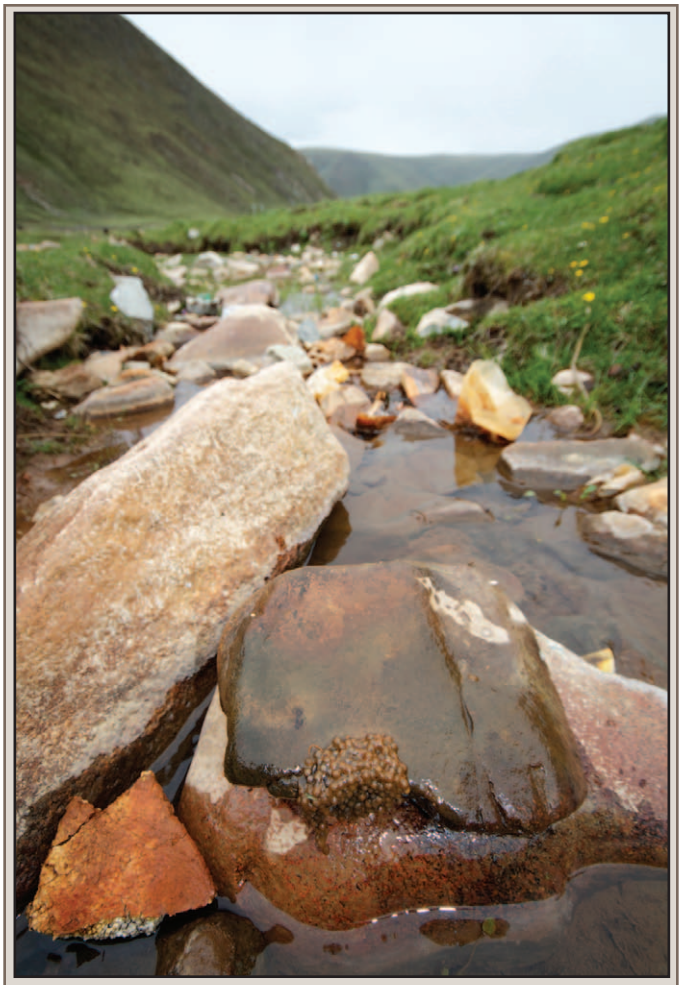

FIG. 2. Overturned *Scutiger boulengeri* nest (lower middle) in Qinghai, China.

***XENOPHRYS BRACHYKOLOS* (Short-legged Toad). DIET.** *Xenophrys brachykolos* is endemic to Hong Kong with a SVL to 6 cm (Karsen et al. 1998. Hong Kong Amphibians and Reptiles. Provisional Urban Council, Hong Kong. 186 pp.). Although the natural diet of this species is unknown, it has been reported to feed on earthworms, crickets, and termites in captivity (Karsen et al. 1998, *op. cit.*). At 2000 h on 15 October 2011, in Pokfulam Country Park (22.268°N, 114.141°E, WGS84; elev. 250 m), Hong Kong, we observed an adult, gravid female *X. brachykolos* (5 cm SVL) sitting on a rock in a stream with a partly ingested earthworm (total length = 26 cm) in its mouth (Fig. 1). The earthworm was still alive and slowly wriggled out of the frog's stomach and eventually escaped. The earthworm appeared to be at least double the body size of the frog by volume and it seemed impractical for the frog to accommodate the whole worm in the stomach

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. Adult female *Xenophrys brachykolos* feeding on an earthworm much larger than its size in Hong Kong. The earthworm was still alive and slowly wriggled out of the frog's stomach and eventually escaped.

even if the earthworm was dead. To our knowledge, this is the first record of such unusual feeding behavior of this species.

Foraging of frogs is stimulated entirely by prey movement (Lettvin et al. 1959. Proc. IRE 47[11]:1940–1955), and frogs will attempt to ingest any prey that fits within its gape width limit. Without the ability to masticate, frogs are sometimes prone to mistakenly tackle prey larger than they can handle. The theory of optimal feeding strategy suggests that prey size selection is governed by the balance between the cost of handling and the benefit of eating the prey (Schoener 1966. Annu. Rev. Ecol. Syst. 2:369–404); therefore predators should not attempt to consume large prey if handling proves too costly, even if they can physically ingest it. Frogs are possibly one of the few taxa that defy this theory. Feeding behavior of this sort, although rarely reported, may occur more often than expected.

TESTUDINES — TURTLES

***CHELONOIDIS CHILENSIS* (Argentine Tortoise). ECTOPARASITE.** *Chelonoidis chilensis* ranges from southwestern Bolivia and western Paraguay south to northwestern Argentina (Bonin et al. 2006. Turtles of the World. Johns Hopkins Univ. Press, Baltimore, Maryland. 416 pp.). It is listed as a vulnerable species on the IUCN Red List of Threatened Species (http://www.iucnredlist.org. Accessed 10 December 2012). Herein, we report a new host record for a tick found on *C. chilensis*.

A hatchling *C. chilensis* (voucher retained by the Museo de Historia Natural, Asunción, Paraguay) was collected by PSF in February 1996, 15.6 km S of Filadelfia and 37.7 km NW on the Ruta Transchaco (Dr. Carlos Antonio López) Highway, Boquerón District, Paraguay (22.3475°S, 60.2545°W; datum WGS84). It was infested with a single tick, which was placed in a vial containing 70% ethanol and sent to CTM. It was later forwarded to LAD for processing and identified as a female *Ambylomma dissimile* Koch, 1844. The specimen is deposited in the U.S. National Tick Collection, Statesboro, Georgia, under accession number RML 122343.

Although *A. dissimile* has been reported previously from amphibians and reptiles in Paraguay (Nava et al. 2007. Ann. Trop. Med. Parasitol. 101:255–270) this is the first time, to our knowledge, that it has been reported from *C. chilensis*. This tick is a common ectoparasite of various Neotropical reptiles and/or amphibians in Central America, the Caribbean, and South America (Guglielmone et al. 2003. Ticks [Acari: Ixodida] of the Neotropical Zoogeographic Region. International Consortium on Ticks and Tick-borne Diseases, Atalanta, Houten, Netherlands. 173 pp.; Voltzit 2007. Acarina 15:3–134). It also occurs in Florida (Keirans and Durden 1998. J. Med. Entomol. 35:489–495).

Butte Creek Road, Scotts Mills, Oregon 97375, USA (e-mail: herps2apes@peoplepc.com).

***CHRYSEMYS PICTA MARGINATA* (Midland Painted Turtle). AVIAN PREDATION.** While conducting road-cruising surveys and systematic transect surveys to estimate reptile abundance from 1 May 2012 to 31 August 2012 on the Magnetawan First Nation, Ontario, Canada, we observed a high number of reptile road mortality events and predation on *Chrysemys picta marginata* by birds (Common Ravens (*Corvus corax*) and American Crows (*Corvus brachyrhynchos*)). The road mortality data are being used for another study; here we report the details of the avian predation events.

A total of 10 successful avian predation events on Painted Turtles (6 females, 2 males, 2 sex unknown) occurred between 27 May 2012 and 11 June 2012. These dates correspond with Painted Turtle nesting season at our site, and the time when males are moving among marshes in search of mates (pers. obs.; Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed., John Hopkins Univ. Press, Baltimore, Maryland. 827 pp). An unsuccessful predation event occurred on 5 June 2012, when researchers chased a murder of American Crows off an adult female Painted Turtle who was flipped onto her carapace on the roadside. As they approached, the researchers noted a bird pecking at the legs of the turtle. The turtle was not injured, thus, it is presumed that the researchers interrupted the predation event.

All of the 10 bodies collected from the successful predation events indicated a consistent method used by the *Corvus* spp. to predate the turtles. Typically, the turtle would be found flipped onto its carapace, and had an open wound in the inguinal space of the hind limbs (Fig. 1). This opening would allow the birds' access to both entrails and eggs within gravid females. We found that the predation event did not immediately kill the turtle, but rather the turtle remained alive for 2–6 h post-predation (timing estimated based on durations between surveys). We found that over half of the individuals with internal organs missing still retained muscular function in their jaws and eyelids; it has been reported that brain function in freshwater turtles can persist for upwards of three hours after blood flow stops (Milton 2008. *In* Proceedings of the Turtle Stewardship and Management Workshop. Toronto Zoo, Toronto, Ontario. 17 pp). Turtles that were found predated but alive were euthanized to prevent further suffering.

As a result of the high intelligence and socialized problem-solving behaviors of *Corvus* spp. (Seed et al. 2008. Proc. Royal Soc. B, 275:1421–1429), and the uncommon occurrence of this method of predation, we suspect that this is a learned behavior

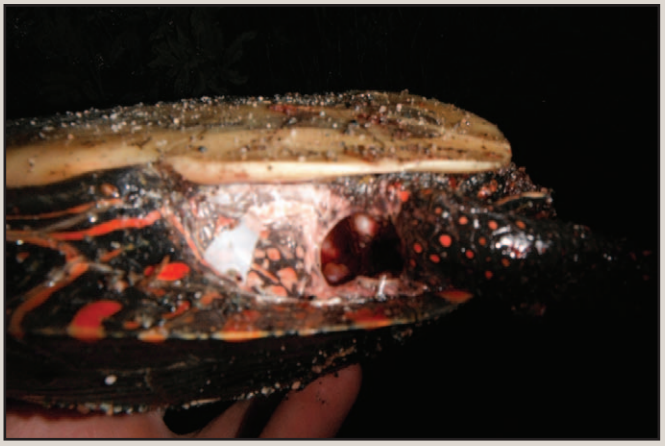

FIG. 1. Predation of *Chrysemys picta marginata* by Common Ravens (*Corvus corax*) and American Crows (*Corvus brachyrhynchos*). The avian predator would create an opening in the inguinal spaces of the hind limbs and then access the entrails and eggs of the turtle through that opening.

seen in the Magnetawan First Nation population (and perhaps other populations) of *Corvus* spp. rather than a genus-wide trait. Corvids have previously been documented to predate freshwater turtle eggs and hatchings (Rollinson and Brooks 2007. J. Herpetol. 41:174–176; Ernst and Lovich 2009, *op. cit.*), and to predate juvenile Desert Tortoises (*Gopherus agassizii*; Boarman and Kristan 2006. Evaluation of Evidence Supporting the Effectiveness of Desert Tortoise Recovery Actions. USGS Scientific Investigations Report 2006–5143, 27 pp.), but we found no published records of corvid predation on adult freshwater turtles. Birds of prey have been documented as avian predators of adult *C. picta* (Ernst and Lovich 2009, *op. cit.*). All of the corvid predation events we recorded occurred during spring, when the turtles are moving terrestrially in search of nest sites (females) or potential mates (males), so presumably the birds are targeting turtles when they out of the aquatic environment and most accessible.

Across North America, turtle populations are in decline (Gibbons et al. 2000. BioScience 50:653–666). Turtle populations rely on high adult survivorship to offset low juvenile recruitment and delayed sexual maturity (Gibbs and Shriver 2002. Conserv. Biol. 16:1647–1652), and any new source of adult mortality observed deserves further investigation, whether the source is anthropogenic (road mortality or habitat destruction) or ecological (invasive or adapting species).

Financial support for this research was provided by Magnetawan First Nation, Laurentian University, the Ontario Ministry of Natural Resources and the Ontario Ministry of Transportation. Jenn Baxter-Gilbert, Sean Boyle, Ron Maleau, and Chris Neufeld are thanked for their field assistance. All research was conducted under an approved Laurentian University Animal Care Committee protocol, and authorized by Magnetawan First Nation's Chief and Band Council and the Ontario Ministry of Natural Resources.

***CHRYSEMYS PICTA MARGINATA* (Midland Painted Turtle), *EMYDOIDEA BLANDINGII* (Blanding's Turtle). HATCHLING MORTALITY.** From 1 May to 31 August 2012, road-cruising and systematic transect surveys were conducted to quantify reptile road mortality. Surveys were conducted in three areas along highways in Ontario, Canada ([i] 13 km of Highway 69/400 in Sudbury District; [ii] 13 km of Highway 69/400 in Parry Sound District; and [iii] 6 km of Highway 529 in Magnetawan First Nation). A total of 173 *Chrysemys picta marginata* and 36 *Emydoidea blandingii* were found on the roads, and of this total, 31 of the *C. picta* (18%) and 1 of the *E. blandingii* (3%) were hatchlings. Of these hatchlings, all but one (97%) were found dead on the road (DOR); the only live hatchling was a *C. picta* found on Highway 529 (the lower traffic road) on 8 June 2012. The DOR hatchlings were found between 3 and 30 May 2012, the time period coinciding with spring nest emergence of *C. picta* in Central Ontario after overwintering within the nest chamber (Riley 2012. M.Sc. Thesis, Laurentian University, Canada), and the movement period of *E. blandingii* hatchlings from upland, terrestrial overwintering sites to wetlands (Paterson et al. 2012. Wildl. Res. 39:408–418). Female turtles are attracted to road-side gravel for nesting (Gibbs and Steen 2005. Cons. Biol. 19:552–556; Gibbs and Shriver 2002. Cons. Biol. 16:1647–1652). This behavior may not only increase the mortality risk to nesting females, but also increases mortality risk to the hatchlings through increased depredation and vehicle impact on roadways (Steen and Smith 2006. Herpetol. Cons. Biol. 1:9–15).

Collisions with vehicles are a known source of mortality for adult turtles, and this mortality can have population-wide effects. For instance, road morality skews sex ratios within populations (Gibbs and Steen, *op. cit.*) and decreases population sizes (Gibbs and Shriver, *op. cit.*). There has been extensive research examining the negative effects of road mortality on turtle populations, particularly pertaining to mortality of breeding females during nesting (Steen et al. 2006. Anim. Cons. 9:269–273; Gibbs and Steen, *op. cit.*; Marchand and Litvaitis 2004. Cons. Biol. 18:758–767). However, little research has documented the threats traffic and roads pose to the hatchling life-stage of turtles. Research on sea turtles has demonstrated that vehicular traffic on nesting beaches can negatively affect hatchlings by compacting substrate and preventing emergence from the nest, by disorienting hatchlings during migration from nest chamber to sea, and even killing hatchlings during collisions (Buckley 2004. Environmental Impacts of Ecotourism. CABI Publishing, New York. 389 pp.; Mann 1977. M.Sc. Thesis, Florida Atlantic University). For freshwater turtles, roads negatively affect eggs and hatchlings by increasing nest depredation (Steen and Smith, *op. cit.*); however, we are not aware of any documented cases of hatchling road mortality from vehicle impact.

The presence and mortality rate of hatchling turtles found on roads in our study was likely an underestimation for two reasons. First, scavengers patrol roadways and quickly remove dead individuals, reducing the likelihood of their discovery (Hubbard and Chalfoun 2012. Herpetol. Cons. Biol. 7:150–156). Second, our methodology did not include road surveys during the fall nest emergence period. Although high hatchling mortality is likely common for turtles (Heppell et al. 1996. Ecol. Appl. 6:556–565), unnaturally high levels of hatchling mortality can exacerbate population declines (Crouse et al. 1987. Ecology 68:1412–1423; Crowder et al. 1994. Ecol. Appl. 4:437–445; Seburn 2007. Recovery Strategy for Species at Risk Turtles in Ontario. Ontario Multi-Species Turtles at Risk Recovery Team, Canada). Roads are known to threaten turtle populations, and our observations demonstrate that these threats are present throughout all life stages of turtles.

We thank Jenn Baxter-Gilbert, Sean Boyle, Ron Maleau, and Chris Neufeld for their field assistance. Financial support for

this research was provided by Magnetawan First Nation, Laurentian University, the Ontario Ministry of Natural Resources and the Ontario Ministry of Transportation. ***CHRYSEMYS PICTA PICTA* (Eastern Painted Turtle). MORPHOLOGY.** Bicephaly, or having two heads, was known for *Chrysemys picta* from at least as far back as the late 1800s (Barbour 1889. St. Nicholas 16:525–527). Here we report the first observation of this morphological anomaly for Maine.

On 26 April 2012, an immature *C. p. picta* was observed moving across the lawn of a residence in Alfred, York Co., Maine, USA. Due to the time of year and the turtle's age (<1 yr old), it likely overwintered in the nest and had recently emerged (Fig. 1). The turtle was brought to a local wildlife rehabilitation center, and although it initially appeared healthy and fed normally with both heads, it died on 20 June 2012. Aside from possessing two heads the only other morphological anomaly observed is the presence of an extra marginal scute on each side of the carapace. The specimen has been deposited at the Yale Peabody Museum (YPM 18600).

FIG. 1. Bicephalic *Chrysemys p. picta* from Alfred, York Co., Maine, photographed on 19 May 2012.

***EMYDOIDEA BLANDINGII* (Blanding's Turtle). FORAGING AND DIET.** *Emydoidea blandingii* is thought to be primarily carnivorous. Although the majority of reported prey consists of invertebrates, a wide variety of vertebrate prey has been documented, including fish, anurans, turtles, and birds. Fish most likely comprise the bulk of vertebrate prey (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins Univ. Press, Baltimore, Maryland. 827 pp.).

On 6 May 2010 an adult *E. blandingii* was observed swimming in a roadside ditch adjacent to a mixed shrub-scrub and cattail (*Typha* sp.) wetland (44.666455°N, 75.229485°W; WGS 84) in St. Lawrence Co., New York, USA. The turtle proceeded to dive below a floating mat of European Frogbit (*Hydrocharis morsus-ranae*) and resurfaced grasping a still moving Central Mudminnow (*Umbra limi*) in its mouth. The turtle then dove below the vegetation mat a second time, where it presumably consumed the *U. limi*. This is the first documented instance of *E. blandingii* preying upon *U. limi*. This observation is significant due to the fact that both species occupy eutrophic, shallow water wetlands and are focally distributed around the Great Lakes region (Ernst and Lovich 2009, *op. cit.*; Hubbs et al. 2004. Fishes of the Great Lakes region, rev. ed. University of Michigan Press, Ann Arbor, Michigan. 276 pp.). Because of this, *U. limi* may be a food source for *E. blandingii* throughout a substantial portion of its range. It is also significant that this predation event occurred in and around the exotic *H. morsus-ranae*, a fairly recent invader of the wetlands of north-central St. Lawrence Co. (Catling and Dore 1982. Rhodora 84[840]:523–545). The presence of *H. morsus-ranae* has been shown to functionally alter invaded wetlands (Catling et al. 1988. Nat. Can. 115[2]:131–137), and may also have unknown effects on the ecology of *E. blandingii*.

***HOMOPUS FEMORALIS* (Greater Padloper). REPRODUCTION.** *The reproduction of Homopus femoralis* has not been systematically studied, but field guides report that the species produces clutches containing up to three eggs in spring (November) and summer, at egg lengths (EL) of 29–36 mm, and egg widths (EW) of 25–27 mm (Boycott and Bourquin 2000. The Southern African Tortoise Book. Privately printed, Hilton, South Africa. 228 pp.; Branch 2008. Tortoises, Terrapins and Turtles of Africa. Struik Publishers, Cape Town. 128 pp.). I radiographed wild females (SCL > 114 mm based on females reproducing in captivity, pers. obs.) from Beaufort West Municipality, South Africa, in December 2008, February 2010 (summer), and October 2011 (spring), and recorded SCL and shell volume (SV, Loehr et al. 2004. Herpetologica 60:444–454) for each individual. I measured pelvic widths (PW), EL, and EW on radiographs to the nearest 0.5 mm, and corrected measurements to actual dimensions (Graham and Petokas 1989. Herpetol. Rev. 20:46) using a focus to film distance of 1000 mm, an egg radius of 13.54 mm, and an estimated distance between film and egg of 5 mm. Egg lengths of some eggs

TABLE 1. Means, standard deviations, and ranges of pelvic widths (mm), clutch and egg dimensions (mm) and volumes (cm^3), in three wild *Homopus femoralis* females.

	Mean	SD	Range	N
Clutch size	3.0	1.73	1–4	3
Clutch volume	36.5	23.01	9.92–50.35	3
Egg length	31.3	2.93	28.0–33.6	3
Egg width	26.6	0.51	26.02–27.0	3
Egg volume	11.6	1.46	9.9–12.6	3
Pelvic width	31.7	1.24	30.4–32.9	3

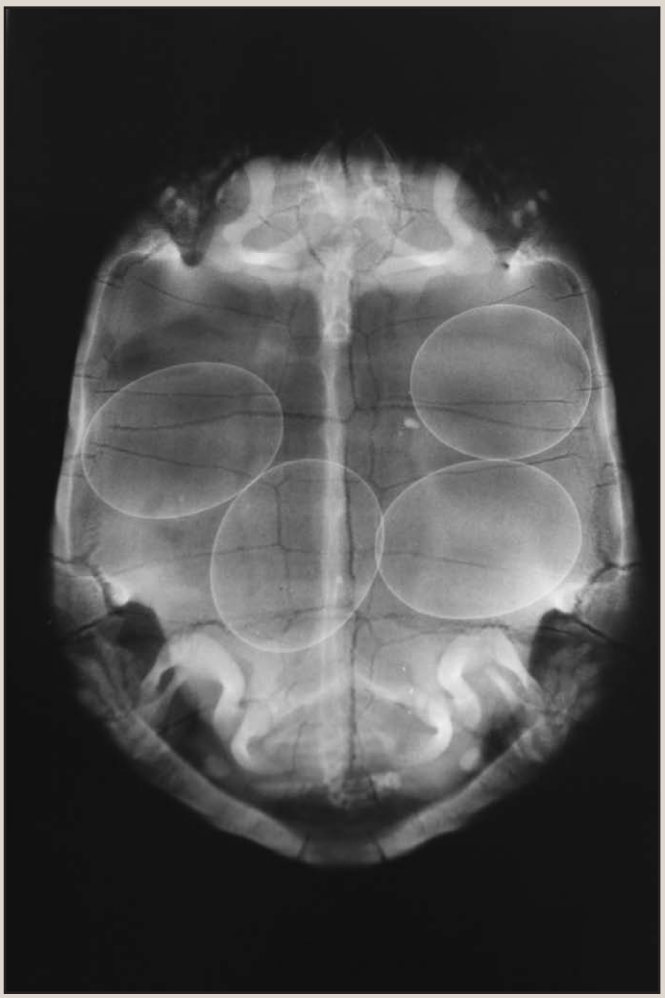

FIG. 1. Radiograph of a female *Homopus femoralis* containing four eggs.

may have been underestimated when long axes of eggs were not parallel to the film plane. The corrected EL and EW was used to estimate egg volume (EV, Loehr et al. 2004, *op. cit.*). To avoid pseudoreplication, mean dimensions for all eggs in a clutch (i.e., eggs with the same level of calcification) were treated as single samples.

Six females (SCL 116.64–137.29 mm; SV 269.15–447.86 cm^3) radiographed in summer did not contain calcified eggs. In spring all three individuals that were radiographed contained calcified eggs: one female (SCL 130.54 mm; SV 392.38 cm^3) contained one egg, and two others (SCL 127.36 and 133.46 mm; SV 389.18 and 393.16 cm^3) each contained a clutch of four eggs (Fig. 1; Table 1). Clutch volume was 2.5–12.8% of SV.

Egg dimensions tended to fall within the range published previously, and their production did not appear to require pelvic kinesis. The recorded clutch size represents a new maximum for the species. Clutch volume relative to SV exceeded the ratio found for congener *Homopus signatus* that produces relatively large eggs (Loehr et al. 2011. Copeia 2011:278–284). The lack of females with calcified eggs in summer may indicate that the species' low activity level (Loehr 2012. Afr. Zool. 47:294–300) enables it to produce only a single clutch annually.

Thanks are extended to Beaufort West Hospital (Marcel van Wyk in particular) for radiographing the tortoises.

VICTOR J. T. LOEHR, Homopus Research Foundation, Kwikstaartpad 1, 3403ZH IJsselstein, Netherlands; e-mail: loehr@homopus.org.

***KINOSTERNON FLAVESCENS FLAVESCENS* (Yellow Mud Turtle). ROAD-CARRION FEEDING.** *Kinosternon flavescens flavescens* is found in almost any quiet water within its range but readily moves over land, occasionally migrating between bodies of water (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 578 pp.). Studies from Oklahoma revealed that the diet of adult *K. flavescens* comprises, by volume, Insecta (27.8%), Crustacea (27.7%), Mollusca (23.5%), Amphibia (9.2%), aquatic vegetation (8.5%), and carrion (3.2%) (Mahmoud 1968. Herpetologica 24:300–305). Given that carrion is such a limited part of the diet of *K. flavescens* and no records of road scavenging were found for any species in the genus *Kinosternon*, herein I describe *K. f. flavescens* scavenging on a dead-on-road (DOR) Striped Skunk (*Mephitis mephitis*).

While driving on 3 July 2010, I noticed a small turtle near the carcass of a Striped Skunk on the shoulder of U.S. Hwy. 82, ca. 1.5 km W of Crosbyton, Crosby Co., Texas, USA. Closer examination revealed that a male *K. f. flavescens* (carapace = 135 mm; plastron = 104 mm) was feeding on the extruded organs of the recently struck Striped Skunk. The turtle and skunk were subsequently moved to the grassy bar-ditch where the turtle began to re-feed on the entrails. Heavy rains occurred in the area during the previous two weeks and probably initiated the *K. f. flavescens* to move between local playa lakes found on either side of the highway. Rainfall is known to stimulate movement in *K. flavescens* (Ernst et al. 1994, *op. cit.*), a behavior also observed in *K. subrubrum* where a mass movement and mass road mortality followed a local "deluge of rain" (Crawford and Doyle 2010. Herpetol. Rev. 41:71). The discovery of the skunk by the *K. f. flavescens* was probably incidental to a post rainfall migration.

Many fully aquatic turtles are known to utilize carrion (Ernst et al. 1994, *op. cit.*) but most are spatially limited to DOR scavenging, whereas tortoises and terrestrial turtles have a more direct access to scavenge DOR carrion. Examples include Gopher Tortoises (*Gopherus polyphemus*) scavenging a dry, flattened Great-horned Owl (*Bubo virginianus*) and an armadillo (*Dasypus novemcinctus*) (Jackson and Ostertag 1999. Herpetol. Rev. 30:40); an Eastern Box Turtle (*Terrapene carolina*) feeding on the entrails of a DOR *Agkistrodon contortrix* (Jensen 1999. Herpetol. Rev. 30:95); an Ornate Box Turtle (*T. ornata*) eating the entrails of a DOR *Bufo cognatus* (Hill and Wilcoxen 2005. Herpetol. Rev. 36:443); and a Desert Box Turtle (*T. ornata luteola*) found on a road with a DOR *Phrynosoma modestum* in its mouth (Germano 2009. Herpetol. Rev. 40:80). Opportunistic scavenging of DOR vertebrates by wandering turtles and tortoises is potentially a significant dietary resource. However, it also encourages turtles to loiter along roadways and is a potential source of mortality in these situations.

STEPHEN KASPER, Lake Alan Henry Wildlife Mitigation Area, City of Lubbock, Lubbock, Texas 79457, USA; e-mail: skasper@mail.ci.lubbock.tx.us.

***KINOSTERNON INTEGRUM* (Mexican Mud Turtle). ECTOPARASITES.** Leeches (Hirudinea) are common ectoparasites of aquatic reptiles, especially of turtles and crocodilians, and can cause anemia, bacterial, and protozoal infections in their hosts (Lane and Mader 1996. *In* D. R. Mader [ed.], Reptile Medicine and Surgery, pp. 185–203. W. B. Saunders Co., Philadelphia, Pennsylvania). In Mexico only 27 species of leeches are known, of which three belong to the genus *Placobdella* (Oceguera-Figueroa et al.

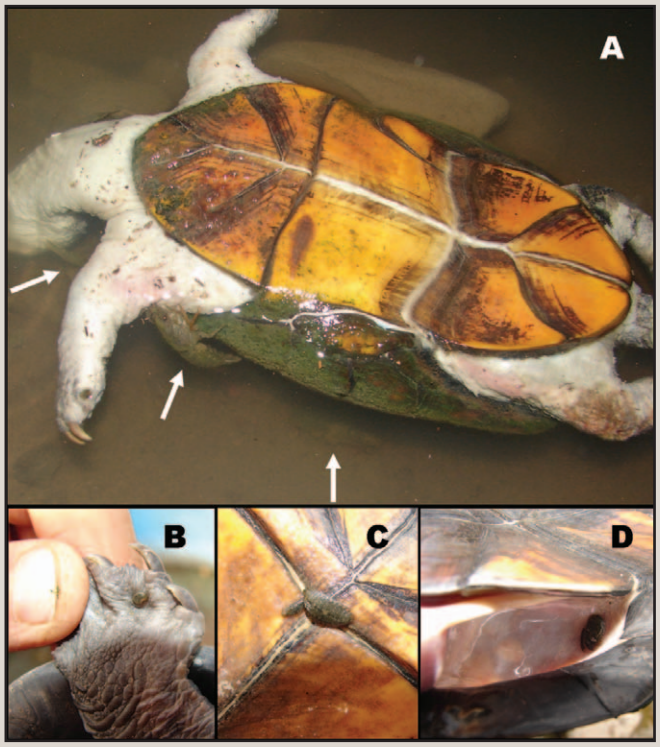

FIG. 1. A) Individuals of *Cambarellus montezumae* tearing tissue from the *Kinosternon integrum* carcass. B) A leech individual on the hind right web foot. C) Two leeches on the plastron surface. D) Leech mass individuals inside of the left hind limb cavity.

2010. Sanguijuelas. CONABIO. Biodiversitas 90:1–5). This genus is well represented in North America, with members that feed almost exclusively on freshwater turtles (Sawyer 1972. Illinois Biol. Monogr. 46:18–23).

Here we report a new host record and mean intensity data for *Placobdella mexicana,* which was previously recorded on *Kinosternon hirtipes* (Lamothe Argumedo et al. 1996. Catálogo de la Colección Nacional de Helmintos. Universidad Nacional Autónoma de México, México), and we document the first record of freshwater crayfish (*Cambarellus montezumae*) feeding on a *K. integrum* carcass.

On 18 August 2012, during fieldwork around a pond's edge in the Municipality of Chapala, Jalisco, México (20.323612°N, 103.218758°W, datum WGS 84; elev. 1790 m), we found one dead adult specimen of *K. integrum* (JLB-R022: carapace length [CL] = 138.80 mm) at 2105 h. The specimen showed a perforation between the fourth and fifth vertebral scute of the carapace, suggesting that death was caused by a gunshot. Upon examination of the carcass we observed adult individuals of crayfish feeding actively on the carcass (Fig. 1A); crayfish specimens were collected and identified as *Cambarellus montezumae* (Saussure, 1857) (Crustacea: Decapoda: Cambaridae). This feeding behavior can be related to their general and opportunistic habits, including cannibalism, previously reported (Gherardi 2002. *In* D. M. Holdich [ed.], Biology of Freshwater Crayfish, pp. 258–290. Blackwell Science, Oxford, UK). Moreover, we found two parasitic leeches on the *K. integrum* carcass, both in soft tissue on the neck; these were collected and identified as *Placobdella mexicana* Moore, 1898 (Hirudinea: Rhynchobdellida: Glossiphoniidae). Additionally, we have five records of living specimens of *K. integrum* parasitized by leeches (*P. mexicana*) found at Chapala's lakeshore on 27 March 2012 (2 specimens) and 18 November 2012 (3 specimens) (20.314078°N, 103.135139°W, datum WGS 84; elev. 1530 m). In these five specimens the mean intensity of infection (mean number of leeches per infected turtle ± SD) was 11.2 ± 16.54 SD, range = 1–44. The affected body parts were the ventral surface of the plastron, and soft tissues of the neck, limbs (specially front and hind limb cavities), and tail (Fig. 1B, C, D).

All samples (crayfish and leeches) were deposited at the Entomological Collection, Centro de Estudios en Zoología, CUCBA, Universidad de Guadalajara (CZUG), and the Colección Nacional de Helmintos, Instituto de Biología, Universidad Nacional Autónoma de México (UNAM). JLB-R was supported by a Scholarship from CONACYT for his Master degree.

***MALACLEMYS TERRAPIN* (Diamond-backed Terrapin). COASTAL EROSION AND NEST MORTALITY.** *Malaclemys terrapin* inhabits coastal salt and brackish marshes from Texas to Massachusetts along the Gulf and Atlantic coasts of the United States (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. John Hopkins Univ. Press, Baltimore, Maryland. 827 pp.). Terrapins usually nest in sandy or porous substrates along coastal beaches, sand dunes, sand spits, or shell islands. In these habitats, nesting usually occurs above mean high tide levels and in areas with little erosion (Burger 1977. Am. Midl. Nat. 97:444–464). However, Roosenburg (1992, Ph.D. dissertation, Univ. of Pennsylvania) and Butler et al. (2004. Am. Midl. Nat. 152:145–155) noted that terrapin nests were sometimes "washed out" by high tides or buried by shifting sand, but nest loss due to large-scale, coastline erosion has not been reported. Herein we report on a terrapin nest that was destroyed by barrier island erosion in coastal Louisiana, with discussion on potential

PHOTO BY ME2 MARK CAMACHO, UNITED STATES COAST GUARD

FIG. 1. Evidence of coastal erosion that has encroached into the nest cavity of a Diamondback Terrapin (*Malaclemys terrapin*) nest on the island of East Grand Terre (Plaquemines Parish, Louisiana).

PHOTO BY A. WHITE

FIG. 2. An example of a rapidly eroding shoreline near the locality of the terrapin nest on East Grand Terre Island (Plaquemines Parish, Louisiana). Note the installed sand fencing—a dune formation and coastal erosion control measure—that is also being lost to coastal erosion.

population-level consequences that coastal erosion may have on Louisiana terrapin populations.

On 15 May 2012, one of us (MC, U.S. Coast Guard) was on the island of East Grand Terre (Plaquemines Parish, Louisiana) and noted an exposed terrapin nest along the edge of an eroding shoreline (29.306541°N, 89.874788°W). MC took a photograph of the nest (Fig. 1) and sent it to the additional authors (BS, AW, JW, and WS), all biologists with the Louisiana Department of Wildlife and Fisheries (LDWF). This was almost certainly a terrapin nest as there is no other nesting turtle species recorded for the island (A. White, unpubl. data). Unfortunately, LDWF biologists could not arrange a boat trip to revisit the site for a month and therefore could not confirm the fate of the nest (i.e., nest failure directly or indirectly linked [nest desiccation] to shoreline erosion). BS searched the location on 13 June 2012 and found no exposed nest, but only an undercut beach shoreline in the nest location. This shoreline is known to be frequently subjected to high rates of erosion during times of unusually high tides and storms (Fig. 2). This nest can be presumed lost, thus this observation represents the first reported terrapin nest destroyed, whether directly or indirectly, by landscape-level coastal erosion.

Unfortunately, the State of Louisiana is losing coastal marshes and barrier islands at alarming rates due to coastal erosion and coastal conversion of land to water. The greatest land losses in coastal Louisiana occur in the Mississippi Deltaic Plain (Barras et al. 2008. USGS Sci. Inv. Map 3019), which also holds the most confirmed terrapin localities in the state (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana State Univ. Press, Baton Rouge. 316 pp.). Land losses have also impacted many barrier island complexes which have been lost or highly degraded over the last few decades (e.g., Chandeleur Islands, Isle Dernieres).

With terrapins using "fringe" brackish and saline marshes that are being lost annually, as well as utilizing rapidly eroding barrier islands for nesting habitat, these factors could detrimentally impact the long-term viability of Louisiana terrapin populations. These factors, along with a paucity of knowledge about terrapins in the state, have led to an increased interest in terrapin research in Louisiana (see Selman and Baccigalopi 2012. Herpetol. Rev. 43:583–588). Current and future research will focus on documenting the distribution and abundance of the species in the state (Selman et al., unpubl. data), as well as documenting nesting beaches and nesting ecology of terrapins in coastal Louisiana (White et al., unpubl. data).

We acknowledge the Office of Wildlife and Office of Fisheries of LDWF for their support of current and future Diamond-backed Terrapin research.

***MALACLEMYS TERRAPIN* (Diamond-backed Terrapin). DREDGING FORAGING BEHAVIOR.** Diamond-backed Terrapins are the only species of turtle specialized to inhabit the brackish coastal ecosystems along the Atlantic and Gulf coasts of North America. They show unique physiological and behavioral adaptations that enable them to live within these saline environments (Cowan 1971. Can. J. Zool. 49:691–697; Cowan 1990. Can. J. Zool. 68:1520–1524; Davenport and Macedo 1990. J. Zool. Lond. 220:487–496; Gilles-Baillien 1973. J. Exp. Biol. 59:39–43; Hart and Lee 2006. Stud. Avian Biol. 32:206–213). Diamond-backed Terrapins also inhabit Bermuda, a group of small islands (32.30889°N, 64.74599°W; WGS 84) situated 965 km ESE of Cape Hatteras, North Carolina, USA. This population, the only one outside the USA, is considered native (Parham et al. 2008. Biol. Lett. 4[2]:216–219) and is found only in four brackish water ponds located at the eastern end of the archipelago. All four bodies of water are situated within a single square kilometer of area on a private golf course and are separated from each other by <380 m of land (MO, unpubl. data).

Diamond-backed Terrapins are carnivorous and feed primarily upon a variety of marine molluscs and crustaceans (namely periwinkles, crabs, mussels, and clams) throughout their North American range (Tucker et al. 1995. Herpetologica 51:167–181; Spivey 1998. M.Sc. thesis, Univ. North Carolina. 80 pp.; Roosenburg et al. 1999. Chel. Cons. Biol. 3:425–429; Petrochic 2009. M.Sc. thesis, Long Island Univ. 66 pp; Butler et al. 2012. Chel. Cons. Biol. 11[1]:124–128; Erazmus 2012. M.Sc. thesis, Hofstra Univ. 46 pp). These studies indicate that there are geographic differences in the diet of terrapins that may reflect variations in prey availability and accessibility. This turtle appears to be a predator that normally uses visual cues while foraging, showing selectivity in the prey that it eats (Davenport et al. 1992. J. Mar. Biol. Assoc. U.K. 72:835–848; Tucker et al. 1995. Herpetologica 51:167–181; Tucker et al. 1997. Amer. Midl. Nat. 138:224–229).

A study investigating the biology, including diet and feeding ecology, of Bermuda's Diamond-backed Terrapins was performed between 2008 and 2012. One of the brackish ponds where the Bermuda population resides (South Pond) is small (0.44 ha), non-tidal, very shallow (mean depth 35 cm), and contains a 0.27 ha grass-dominated marsh in its center. The annual salinity (measured with an optical refractometer) averaged 10.8 practical salinity units during this period, and the water clarity was often very good, which presented excellent opportunities for observing the terrapins. South Pond has also been incorporated as a water hazard feature on the golf course for the past eight decades. The terrapins that reside in this pond have become habituated to the frequent presence of people and readily forage in

the presence of observers. During the five-year study period, terrapins were commonly observed moving slowly along the bottom of the pond taking successive mouthfuls of sediment during both diurnal and nocturnal surveys. The head was often buried within the sediment during this behavior. The benthic sediment in South Pond is gelatinous and sapropelic, consisting of highly organic mud and detritus. It also contains the deposit-feeding thiarid gastropod *Melanoides tuberculata*, a non-native burrowing species that is known to reach densities <23,000 m^{-2} (Roessler et al. 1977. Florida Sci. 40[1]:87–94). *Melanoides tuberculata* is parthenogenetic and viviparous; breeding females (5+ mm shell length) release large numbers of juveniles (1–2 mm shell length) (Appleton et al. 2009. Zool. Meded. 83:525–536).

Such dredging-style foraging behavior has not been reported in the scientific literature before, possibly because the inconspicuous nature of Diamond-backed Terrapins, together with the turbid waters of the brackish coastal environments in North America where they feed, have precluded effective foraging observations in the wild. It is evidently a behavioral adaptation that has allowed terrapins in Bermuda to take advantage of the small benthic gastropods inhabiting the gelatinous pond sediment. Given the small size and burrowing habit of these gastropods, we propose that Bermuda's terrapins are haphazardly consuming the sediment ("deposit-feeding") in a manner that increases the chances of incidentally ingesting the small gastropods found within it. In support of this hypothesis, we have conducted fecal analyses that confirm that Bermuda's terrapins are consuming high numbers of small *M. tuberculata*, together with large quantities of sediment (MO, unpubl. data). This foraging behavior is inevitably exposing them to harmful contaminants (particularly heavy metals, gasoline-range and diesel-range petroleum hydrocarbons, and polycyclic aromatic hydrocarbons) that have been found within this medium (Fort et al. 2006. Appl. Herpetol. 3:143–172; J. Bacon, pers. comm.).

OUTERBRIDGE, Department of Conservation Services, 17 North Shore Road, Flatt's Village, FL04, Bermuda (e-mail: mouterbridge@gov.bm); **JOHN DAVENPORT**, School of Biological, Earth and Environmental Sciences, University College Cork, North Mall Campus, Cork, Ireland (e-mail: j.davenport@ucc.ie).

***PHRYNOPS GEOFFROANUS* (Geoffroy's Side-necked Turtle). ENDOPARASITE.** *Phrynops geoffroanus* is a freshwater chelid turtle that occurs in South America from Colombian Amazonia to the Brazilian state of Rio Grande do Sul, and from Uruguay to northern Argentina (Lema and Ferreira 1990. Acta Biol. Leopoldensia 12:125–164; McCord et al. 2001. Rev. Biol. Trop. 49:715–764). It inhabits the shallow areas of both lakes and rivers (Pritchard and Trebbau 1984. The Turtles of Venezuela. Society for the Study of Amphibians and Reptiles, Oxford, Ohio. 403 pp.; Ernst and Barbour 1989. Turtles of the World. Smithsonian Institution Press, Washington. 313 pp.). In Brazil, this species can be common in rivers in urban areas (Souza and Abe 2001. Stud. Neotrop. Fauna Environ. Ecol. Syst. 36:57–62.; Lisboa et al. 2004. Arq. Inst. Biol. 71:392–393). The trematode parasites of Brazilian *P. geoffroanus* are apparently poorly known. Between 2006 and 2007, six specimens of *P. geoffroanus* that were already deposited in the Coleção Herpetológica of the Departamento de Zoologia, Universidade Federal de Juiz de Fora (UFJF) (CHLZ - UFJF 564–568, 570) were necropsied. All specimens are from the municipality of Juiz de Fora, Minas Gerais state, Brazil (21.68888°S, 43.34444°W). Trematodes were collected from the small intestine of two male adult host specimens (prevalence: 33.5%, mean intensity: 4 parasites per infected host). After collection, the parasites were fixed in AFA (70% ethanol, 93 parts; 37% formalin, 5 parts; glacial acetic acid, 2 parts) for 48 h, and preserved in 70% ethanol. For identification, the parasites were stained in Delafield's hematoxylin or Mayer's carmalum and mounted in Canada balsam for examination as whole mounts. Voucher specimens (CHIOC 37838) were deposited in the Instituto Oswaldo Cruz Helminthological Collection (CHIOC), Rio de Janeiro, Brazil. All parasites were identified as *Cheloniodiplostum* sp. (Digenea, Proterodiplostomidae) according to Gibson et al. (2002. Keys to the Trematoda, Volume 1. CABI Publishing, London. 544 pp.). In Brazil, previous publications have reported the trematode *Cheloniodiplostomum testudinis* (Dubois, 1936) in unidentified host turtles (Dubois 1936. Rev. Suisse Zool. 43:507–515; Travassos et al. 1969. Mem. Inst. Oswaldo Cruz 67:1–886). *Cheloniodiplostum brevis* (MacCallum, 1921) is the only species of this genus that has been recorded in *P. geoffroanus*, from Colombia (Dubois 1978. Rev. Suisse Zool. 85:607–615). Therefore, this report represents the first Brazilian record for parasitism by *Cheloniodiplostomum* sp. specifically in *P. geoffroanus*.

***PHRYNOPS TUBEROSUS* (Cotinga River Toad-headed Turtle). BIFID TAIL.** Axial bifurcation is the result of a mutation or developmental error in the embryonic development of organisms that may lead to the emergence of bizarre morphology such as two-headed animals (Buffetaut et al. 2007. Biol. Lett. 3:80–81; Wallach 2007. Bull. Maryland Herpetol. Soc. 43[2]:57–62). This phenomenon can also lead to bifid tails in chelonians (Kuchling 2005. Chelon. Cons. Biol. 4[4]:935–937). These animals do not demonstrate true tail autotomy, but a case of regeneration of this body part and subsequent formation of a bifurcated tail is found in the literature (Kuchling 2005, *op. cit.*). Rahman (2011. Herpetol. Rev. 42[2]:265) also noted the occurrence of bifid tail in *Chelydra serpentina*, but the cause of the split was not determined. Here we report the occurrence of bifid tails in individuals of *Phrynops tuberosus* captured in field expeditions conducted in April, June, and July 2012. This is apparently the first record of bifid tails in South American chelids.

We captured four adult *P. tuberosus* (three males and one female) with bifid tails in the Banabuiu River, in the village of Laranjeiras, Ceará, Brazil. The animals had straight-line carapace lengths of 21.05 cm, 24.06 cm, 23.8 cm, and 17.4 cm, respectively. The bifid tails found in this study were of normal length and width, but their tips were duplicated in the horizontal plane. This pattern is very similar to that reported for *C. serpentina* by Rahman (2011, *op. cit.*).

The lack of difference in size between the bifid tails and normal ones suggests that the cause of this phenomenon may be axial bifurcation. However, the repetition of the event (in four

animals) may raise doubt about this explanation, because the probability of such mutations is presumably low. The occurrence of cartilaginous regeneration of an injured tail can also lead tail bifurcation tails in chelonians (Kuchling 2005, *op. cit.*). However, we were unable to do X-ray examination of these turtles, preventing a more precise diagnosis. The regeneration pattern reported by Kuchling (2005, *op. cit.*) is similar to that found in lizards, wherein the missing part is replaced by fibrous or cartilaginous or calcified tissue (Zug et al. 2001. Herpetology: An Introductory Biology of Amphibians and Reptiles. Academic Press, New York. 630 pp.). If the cases reported here were confirmed to be based on regeneration, it would be the second record of this ability in a chelid turtle. Studies on tail bifurcation in turtles could someday reflect on questions of the phylogenetic history of tail autotomy and regeneration in amniotes.

We acknowledge Djan Zanchi Silva and James Harding for providing valuable comments on the manuscript and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for the scholarship that helped fund this study.

***STAUROTYPUS TRIPORCATUS* (Giant Musk Turtle; Guao de Tres Filas). PREDATION.** *Staurotypus triporcatus* is a large freshwater turtle that occurs on the Atlantic versant from central Veracruz, Mexico, to northwestern Honduras. Adults can reach 400 mm carapace length (Iverson 1983. Cat. Amer. Amphib. Rept. 328.1–328.2), and apparently have few documented natural predators. Pritchard (1979. Encyclopedia of Turtles. T.F.H. Publishing, Neptune, New Jersey. 895 pp.) wrote that the "massively constructed" shell of this species "lessens the likelihood of the turtle being cracked and eaten by the crocodiles with which it shares much of its habitat." However, it is well known that humans use the meat of this turtle as a food source (Moll and Moll 2004. The Ecology, Exploitation, and Conservation of River Turtles. Oxford University Press, New York. 393 pp.). Here we provide evidence of natural predation on an adult *S. triporcatus* by a Jaguar (*Panthera onca*) in northwestern Honduras.

At 1431 h on 15 October 2011, a camera trap (Moultrie Game Spy I-65s) set by Panthera staff at "Cerro Agua Caliente," Jeannette Kawas National Park, Atlántida (15.8622°N, 87.6838°W; 30 m elev.) captured an image of an adult female *Panthera onca* carrying an adult *Staurotypus triporcatus* in its mouth (Fig. 1) in a seasonally flooded swamp forest. Jaguars can be individually identified by the shape and pattern of their marks (Silver 2004. Assessing Jaguar Abundance Using Remotely Triggered Cameras. Wildlife Conservation Society, Bronx, New York. 25 pp.). This female was first photographed during August 2010 and has been monitored in the park since then. During October 2011 she was again photographed several times in the "Cerro Agua Caliente" area in company with a cub of about 3 months age. It has been estimated that a jaguar can eat between 1.2 and 1.5 kg of meat per day (Sunquist and Sunquist 2002. Wild Cats of the World. University of Chicago Press, Chicago, Illinois. 452 pp.); a Giant Musk Turtle can weigh up to 10 kg, including the plastron and carapace (Vogt 1997. *In* González Soriano et al. [eds.], Historia Natural de Los Tuxtlas, pp. 494–495. Universidad Nacional Autónoma de México, Ciudad de México), thus having the potential to be an important food item for Jaguars. Moreover, large prey species such as tapirs (*Tapirus bairdii*) and peccaries (*Pecari tajacu, Tayassu pecari*) have been extirpated from Jeannette Kawas National Park, and White-tailed Deer (*Odocoileus virginianus*) are severely declining; all due to human hunting pressure and deforestation. Jaguars are known to prey on turtles, with sea turtles, freshwater turtles, and terrestrial turtles having been documented as part of the Jaguar's diet (Emmons 1989. J. Herpetol. 23:311–314; Wainwright 2002. The Mammals of Costa Rica, A Natural History and Field Guide. Cornell University Press, Ithaca, New York. 454 pp.). However, to the best of our knowledge, this is the first report of Jaguar predation on *S. triporcatus*. The presence of *S. triporcatus* in the Jeannette Kawas National Park has also been confirmed from two specimens collected there. The only other large freshwater turtle in the area is the snapping turtle, *Chelydra rossignonii*; we identified the turtle in the picture as *S. triporcatus* due to the lack of a long tail and the presence of strong carapacial keels.

FIG. 1. A camera trap image of a female *Panthera onca* carrying an adult *Staurotypus triporcatus*, Jeannette Kawas National Park, northwestern Honduras.

CROCODYLIA — CROCODILES

***ALLIGATOR MISSISSIPPIENSIS* (American Alligator). LONG TERM SURVIVAL OF FARM-RELEASED JUVENILE.** The state of Louisiana has an alligator management program that includes a regulated harvest of wild alligators, a nuisance alligator removal program, and a commercial alligator farming program (Elsey and Kinler 2004. *In* Crocodiles. Proc. 17th Working Meeting Crocodile Specialist Group, pp. 92–101. IUCN—The World Conservation Union, Gland, Switzerland and Cambridge UK). An integral facet of the commercial alligator farming program allows for the collection of eggs from the wild, with mandatory release of a portion of juvenile alligators hatched from collected eggs, as a "head-start" program to ensure recruitment of the species (Elsey and Kinler 2011. *In* P. S. Soorae [ed.], Global Re-introduction Perspectives: 2011. More Case Studies from Around the Globe, pp. 125–129. Gland, Switzerland: IUCN/SSC Re-introduction Specialist Group and Abu Dhabi, UAE: Environment Agency-Abu Dhabi). Each of the juvenile alligators released from alligator farms are measured, the sex is determined and recorded, and the alligators are marked with monel tags placed between the toes

of the hind legs and also marked by tail notching (Elsey and Kinler 2011, *op. cit.*). The juvenile alligators (allowable size range of 91.4–152.4 cm total length [TL] at release) are then released back to the wetlands from which the eggs were collected one or two years earlier.

Over time, we have observed that many of the released juveniles grow to adult size and are subsequently caught by alligator trappers in the annual regulated harvest. On 7 September 2012, a tagged alligator was reported to our agency. The web tag was from a male alligator that was marked and released on 1 May 1992 (then 124 cm TL) and harvested over twenty years, four months later (7434 days, now 244 cm TL). To our knowledge this is the longest time interval for a recovery of a farm-released alligator from Louisiana's egg ranching program, indicating long-term survival after release to the wild.

The interval growth was somewhat below average for this species (Elsey et al. 1992. Comp. Biochem. Physiol. 103A:667–672). However, coastal southeast Louisiana has been adversely affected by four major hurricanes in recent years (Hurricanes Katrina and Rita in 2005, and Hurricanes Gustav and Ike in 2009); thus high salinity conditions post-hurricanes could have stressed some alligators and slowed normal feeding and growth (Lance et al. 2010. J. Exp. Zool. 313A:106–113; Lauren 1985. Comp. Biochem. Physiol. 81A:217–223). Confirmation was obtained from the person reporting the harvest of the alligator that the alligator's total length was accurate, and no portion of the tail was missing.

We have recovered farm-released alligators that have grown longer than the case herein; the largest recovery we have obtained that held the web tag over time was 381.0 cm when harvested on 10 September 2006 (Elsey 2006. Croc. Spec. Grp. Newsltr. 25:16–17). This male alligator had been tagged and released 4761 days earlier on 28 August 1993, at which point the TL was 111.8 cm. Many alligators lose the monel tags placed in the webbing of the rear feet as they grow, thus precluding knowledge of exact time intervals between release and recovery. Use of year-specific tail notches have been used in our program since 1994 to assist in providing some time interval data when marked alligators lose their foot/web tags.

The properties on which the alligator was released (Poverty Flats) in Terrebonne Parish, Louisiana and on which it was recovered (Rebecca) are in close proximity to each other, and are both irregularly shaped, thus the distance moved between release and recovery can only be estimated. Precise GPS locations are not available at either release or recovery sites, but the minimum distance between the two properties is approximately 0.4 km, while the maximum distance is approximately 12.1 km. Although instances of long-distance dispersal have been documented in alligators, in many cases alligators do not move long distances over time (Lance et al. 2011. Southeast. Nat. 10:389–398), and some females show evidence of strong nest site fidelity (Elsey et al. 2008. Southeast Nat. 7:737–743).

The egg ranching program in Louisiana, which allows for the collection of alligator eggs from privately owned wetlands began in 1986, with the first juvenile alligators being released to the wild in 1988 (Elsey et al. 1992, *op. cit.*). Thus it is possible that many alligators from that first cohort may still be surviving, and not yet recovered, as only a small portion of the population is harvested each year in the annual harvest. The recovery of a farm-released alligator having survived over twenty years (and presumably having fathered numerous clutches of eggs over that time interval, adding to population recruitment) lends support to the philosophy of sustained use management of this valuable resource.

I thank Dawn B. Ledet and staff at Daneco (Houma, Louisiana) for reporting the alligator described in this report, and Will Selman and Bruce Davis for review of an earlier draft of the manuscript.

RUTH M. ELSEY, Louisiana Department of Wildlife and Fisheries, Rockefeller Wildlife Refuge, 5476 Grand Chenier Highway, Grand Chenier, Louisiana 70643, USA; e-mail: relsey@wlf.la.gov.

***ALLIGATOR MISSISSIPPIENSIS* (American Alligator). INTERSTATE MOVEMENT OF ALLIGATORS.** The state of Louisiana has an alligator management program administered by the Louisiana Department of Wildlife and Fisheries (LDWF) that includes a regulated harvest of wild alligators, a nuisance alligator removal program, and a commercial alligator farming program (Elsey and Kinler 2004. *In* Crocodiles. Proceeding of the 17th Working Meeting Crocodile Specialist Group, pp. 92–101. IUCN—The World Conservation Union, Gland, Switzerland and Cambridge, UK). Many other southeastern states also have significant alligator populations, and most states conduct regulated harvests and nuisance control programs; some also allow commercial alligator farming. An integral facet of the commercial alligator farming program in Louisiana allows for the collection of eggs from the wild, with mandatory release of a portion of juvenile alligators hatched from collected eggs, as a "head-start" program to ensure recruitment of the species (Elsey and Kinler 2011. *In* P. S. Soorae [ed.], Global Re-introduction Perspectives: 2011. More Case Studies from Around the Globe, pp. 125–129. IUCN/SSC Re-introduction Specialist Group Gland, Switzerland, and Environment Agency-Abu Dhabi, UAE). Each of the juvenile alligators released from alligator farms in Louisiana are measured, the sex is determined and recorded, and marked with monel tags placed between the toes of the hind legs and also marked by tail notching (Elsey and Kinler 2011, *op. cit.*). The juvenile alligators (allowable size range at release of 91.4–152.4 cm total length) are then released back to the wetlands from which the eggs were collected one or two years earlier.

Over time, we have observed that many of the released juveniles grow to adult size and are subsequently caught by alligator trappers in the annual regulated harvest in Louisiana (Elsey et al. 2001. *In* Grigg et al. [eds.], Crocodilian Biology and Evolution, pp. 426–441. Surrey Beatty & Sons, Chipping Norton, NSW). Additionally, other farm-released alligators are captured occasionally as "nuisance" or problem alligators (Elsey 2007. Herpetol. Bull. 102:11–14) causing human safety concerns.

We herein report on five cases of alligators with interstate movement between Louisiana (LA) and Mississippi (MS), USA. The initial case involved a nuisance trapper in Mississippi harvesting an alligator released from a farm in Louisiana. On 17 July 2008, a Warren Co., MS conservation officer trapped a 348.0 cm male alligator (Fig. 1) in Halpino Lake (just south of Eagle Lake, MS); capture site coordinates were 32.46070°N, 91.00877°W. The foot/web tag (LDWF 222285) was from a juvenile alligator released from a Louisiana alligator farm almost 12 years earlier on 22 July 1996 at which time the total length was 116.8 cm; it was released at Lake St. Joseph in Tensas Parish, 48 km away.

On 11 April 2012, a tagged alligator caught by a licensed Louisiana nuisance alligator trapper was reported to LDWF. The web tag reported (07301) did not match any records of farm-released alligators in Louisiana; nor did the tag match any records of native wild alligators caught and marked/tagged for

PHOTO COURTESY OF COREY HUNT

FIG. 1. Adult male American Alligator (348 cm TL) captured in Mississippi almost 12 years after release to the wild from a farm in Louisiana. Tail notches are clearly evident.

FIG. 2. Map showing release location of an American Alligator marked for research in Mississippi (M), and recovered by a nuisance trapper in Louisiana (L) over three years later. Eagle Lake, MS and Lake Providence, LA locations indicated for reference.

research purposes. The trapper reported the alligator had a numbered cattle tag in the tail as well as another tag with a series of numbers determined as possibly a telephone number; the first three digits were recognized as a Mississippi area code. LDWF staff (RME) then called the alligator program leader in Mississippi (RF), who confirmed the alligator had been initially captured, marked, and released at Pervis Lake in Warren Co., MS (32.48384°N, 91.06619°W) as part of their research program. The male alligator's initial total length was 232.4 cm when marked on 18 March 2009; it was 279.4 cm when captured in Louisiana near Lake Providence in East Carroll Parish in northeast Louisiana, bordering Mississippi. The alligator thus moved at least 49 km between Mississippi and Louisiana, and likely had traveled nearly 71 km by water between sites (Fig. 2).

In September 2012, we documented three additional cases of alligators with interstate movement from harvest information provided by licensed recreational alligator hunters in Mississippi. On 7 September, a 308 cm male alligator was harvested on the Big Black River near Grand Gulf/Port Gibson, MS with LDWF web tag 597115 in the foot. This alligator had been tagged at an alligator farm and released on Sunflower Plantation in Tensas Parish, LA on 17 August 2004 at which point the total length was 132.1 cm. The distance moved over the eight- year interval was approximately 23 km.

On 7 September 2012, two Louisiana farm-released alligators were caught in Mississippi, north of Port Gibson (north of where the Big Black River enters the Mississippi River); both had been released by a Louisiana alligator farmer in nearby Tensas Parish. The alligators were harvested by a trapping team in the same location. The first alligator caught that evening was a 304.8 cm male that had been released on Somerset Plantation at 172.7 cm TL on 29 May 2003 (LDWF tag 529134). The alligator caught later that night was a female that measured 188.0 cm TL, and which had been released on Sunflower Plantation on 13 April 2010 at 129.5 cm TL (LDWF tag 853250). The male was caught approximately 6–7 km from the release site in Louisiana, while the female was recovered some 5 km from the release location.

We are not aware of other cases documenting natural interstate movement of alligators; although in September 2008, Hurricane Ike displaced an alligator released from a farm in southwest Louisiana 489 km to Padre Island National Seashore in lower Texas (Elsey and Aldrich 2009. Southeast. Nat. 8:746–749). It may be that many alligator tag and release studies conducted by state or federal government employees are conducted within the confines of their state property; possibly within a given National Wildlife Refuge or Wildlife Management Area, and thus the opportunities to live capture alligators that have moved off the study site are limited. It was fortunate that we were aware of alligator tagging programs in the adjacent state and could advise accordingly when an alligator from the other state was recovered.

Unusually high snowfall in the United States in 2010–2011 and very high water levels in the Mississippi River during spring 2011 may have allowed for increased movement of alligators over floodplains between Louisiana and Mississippi that year. Also, gradual expansion of Mississippi's wild alligator harvest program from 30 alligators harvested in 2005 to 617 alligators harvested in 2012 has allowed additional opportunity for harvest and recovery of alligators that have dispersed from adjacent Louisiana.

Prior studies have documented alligator movement patterns that can vary widely. Although instances of long-distance dispersal have been documented, in many cases adult alligators do not move long distances over time (Chabreck 1965. Proc. Southeast. Assoc. Fish Wildl. Agencies 19:102–110; Lance et al. 2011. Southeast. Nat. 10:389–398), and some females show evidence of strong nest site fidelity (Elsey et al. 2008. Southeast. Nat. 7:737–743). Indeed, in this report two alligators moved over 40 km; one moved approximately 23 km, while two others moved only 5–6 km.

Due to the magnitude of the farm-release program in Louisiana (often 40,000 or more alligators released each year), precise GPS locations are not available for each alligator at release sites. Also, oftentimes the properties on which the alligators are released are irregularly shaped, thus the distance moved between release and recovery can only be estimated, thus distances discussed herein are minimum estimated dispersal distances.

The relatively long time interval for several of the recoveries of farm-released alligators from Louisiana's egg ranching program described above (8, 9, and 12 years) indicates good survival after release to the wild. We recently described a case with an alligator recovered over 20 years after release to the wild from a farm

setting (Elsey 2012. Herpetol. Rev. 44:309–310). Additionally, the growth to the very large size classes of the male alligators in the cases described (279–348 cm TL) suggests they adapted well to the wild environment after release, and presumably added to population recruitment by having fathered numerous clutches of eggs over that time interval, lending support to the philosophy of sustained use management of this valuable resource.

RUTH M. ELSEY, Louisiana Department of Wildlife and Fisheries, Rockefeller Wildlife Refuge, 5476 Grand Chenier Highway, Grand Chenier, Louisiana 70643, USA (e-mail: relsey@wlf.la.gov); **RICKY FLYNT**, Mississippi Department of Wildlife, Fisheries, and Parks, 1505 Eastover Drive, Jackson, Mississippi 39211, USA (e-mail: rickyf@mdwfp.state.ms.us).

***CROCODYLUS NILOTICUS* (Nile Crocodile). DIET.** The diet of Crocodylus niloticus has been relatively well documented throughout its range on the mainland of continental Africa (Corbett 1959. Proc. R. Entomol. Soc. 34:17–22; Cott 1961. Trans. Zool. Soc. London. 29:211–356; Games 1990. Unpubl. D. Phil. manuscript. University of Zimbabwe; Hutton 1987. J. Anim. Ecol. 56:25–38; Poole 1989. Ospreys: A Natural and Unnatural History. Cambridge University Press, New York; Shine et al. 2001. Oryx 35:260–262; Wallace and Leslie 2008. J. Herpetol. 42:361–368; Whitfield and Blaber 1979. Copeia 1979:266–269). However, in stark contrast with the abundance of literature from the mainland, this apex predator has been poorly studied in Madagascar and specific information on diet remains scarce from this region.

At ca. 1730 h on 23 July 2011 at a lake adjoining our field camp in the Matsedroy Forest (15.48772°S, 46.64752°E, WGS 84; elev. 19.4 m), a 1.5–2 m *Crocodylus niloticus* was observed predating a Malagasy Jacana (*Actophilornis albinucha*). The crocodile attacked from below in a relatively shallow (<3 m) part of the lake that was densely covered by water hyacinth (*Eichornia* sp.). It took approximately five minutes for the crocodile to seize, drown, and consume the Jacana.

While it stands to reason that Malagasy Jacanas and other species of wading birds present at these lakes should comprise part of the diet of the crocodiles that inhabit them, as far as we are aware this is the first record of *C. niloticus* predation on a Malagasy Jacana. Interestingly, this is also the first positive identification of a predator of *Actophilornis albinucha*. *A. albinucha* is a member of Madagascar's endemic avifauna and therefore this observation also contributes to the known literature of predator-prey interactions of endemic fauna in this highly threatened landscape.

We thank the Transitional Government of Madagascar, the Ministère de l'Environnement et des Forêts for allowing us to undertake this work (permit 54710/MEF/SG/DGE/DREF.BOE), Operation Wallacea for funding, Development and Biodiversity Conservation Action for Madagascar (DBCAM) for logistics, and our local guides and team at Mahamavo.

***CROCODYLUS POROSUS* (Saltwater Crocodile). FISHING BEHAVIOR.** A form of fishing behavior not previously described for *Crocodylus porosus* was observed repeatedly on separate occasions at Cahill's Crossing on the East Alligator River in Kakadu National Park, Northern Territory of Australia (12.4844°S, 131.7240°E) from August to October 2012. The behavior was witnessed most frequently around high springs tides, when incoming and then outgoing tidal flow crossed an artificial road barrage that fords the river. A number of fish species, primarily Diamond-scale Mullet (*Liza vaigiensis*) take the opportunity to cross this barrier in relatively high densities, and crocodiles mass both upstream and downstream of the barrage to feed upon them. During our observations, many crocodiles adopted a distinctive body posture while floating at the surface: the back legs extended outwards in a loose R-shape on the same plane as the body; the front legs held out perpendicular to the body, with palms facing outwards and toes projecting upwards out of the water (Fig. 1); the jaws held partially open, with the upper jaw resting on the surface and the lower jaw hanging below the water. This posture could be clearly seen with sufficient water clarity, which is the case immediately prior to the incoming tide flooding over the barrage. The primary mechanism of the posture appeared to be improved detection and capture of fish within striking range that were detected by sensitive mechanoreceptors (integumentary sense organs; ISOs). Fish that swam close to the crocodile's head and touched the front legs or feet were immediately seized by a sideswipe of the head towards the touch. The small, tightly packed scales on the feet provide a high density of ISOs (Leitch and Catania 2012. J. Exp. Biol. 215:4217–4230), which perhaps explains the outward extension of the feet and toes to maximize detection of fish passing within range or breaking the surface. This behavior has only previously been described in the Paraguayan Caiman (*Caiman yacare*) (Olmos and Sazima 1990. Copeia 1990:875–877) and is a fishing strategy that is particularly effective with higher densities of fish.

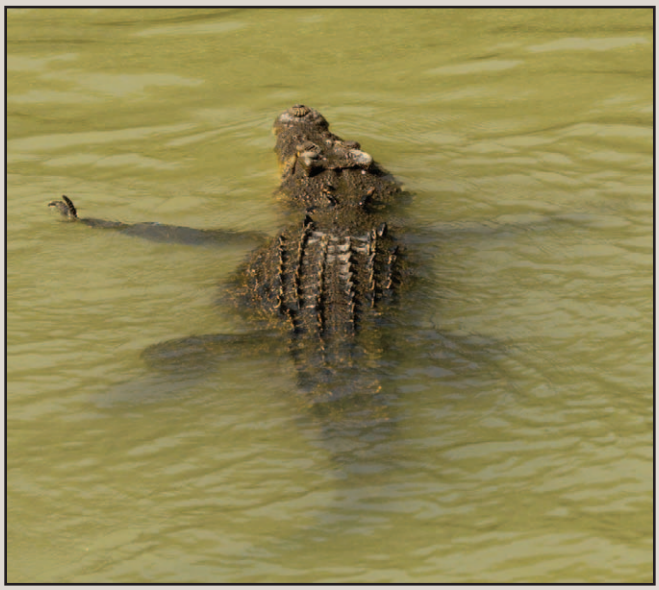

FIG. 1. Adult Saltwater Crocodile (*Crocodylus porosus*) in floating fishing posture.

ADAM BRITTON (e-mail: abritton@crocodilian.com) and **ERIN BRITTON** (e-mail: erin@crocodilian.com), Big Gecko, PO Box 1281, Howard Springs, Northern Territory 0835, Australia.

SQUAMATA — LIZARDS

***ANADIA BOGOTENSIS* (Bogota Anadia Lizard). NESTING.** *Anadia bogotensis* is a common lizard endemic to Colombia and is distributed in areas of highland Andean scrubland and paramo throughout Cundinamarca, Boyacá, and Santander in Colombia, between 2500–3900 m altitude. Despite being common, little is

known of the natural history of this species (Clavijo and Fajardo 1981. Contribución al conocimiento de la biología de *Anadia bogotensis* [Peters] [Sauria, Teiidae]. Tesis de pregrado. Universidad Nacional de Colombia, Bogotá D.C.; Moreno-Arias 2009. Final report project: Conservation status of highland lizards from Sabana de Bogotá, The Rufford Small Grants Foundation, London, UK. 6 pp.; Sánchez et al. 1995. *In* J. O. Rangel [ed.], Colombia Diversidad Biótica I, pp. 277–325. Universidad Nacional de Colombia, Instituto de Ciencias Naturales, Bogotá D.C.). Here I report communal egg-laying in *A. bogotensis* (Fig. 1) under rocks, low necromass and between clumps of grass in two areas within Andean scrubland paramo transition zone and rocks, the first area in the Vereda Las Moyas, municipality of La Calera, Department of Cundimanarca, Colombia (4.66267°N, 74.01615°W; datum WGS 84), and second area in the Vereda Santa Bárbara, Usme locality, rural area southeast of the city of Bogotá D.C., Department of Cundimanarca, Colombia (4.40639°N, 74.14472°W; datum WGS 84).

At the first site, studied between 30 July and 5 November 2006, I found 21 nests averaging 12 viable eggs (range = 2–54 eggs) at different stages of development and I have found evidence of continuous use of these nests, as older eggs were found among 26–578 eggs already hatched at different times (55 older eggs on average). Old eggs were qualified as dead eggs at different stages of decomposition (e.g., discolored, empty, crushed, or beneath new eggs). At the second site, studied between 2 March and 5 May 2009, I found 15 nests more spatially separated averaging six viable eggs (range = 1–18 eggs) at different stages of development. I also found evidence of continuous use of the nests at this site, as older eggs were found among 6–27 eggs that had already hatched at different times (nine older eggs on average). In lizards, communal nests have been observed in various families, but few studies report data for female individuals representing different ages depositing eggs in the same nest cavity simultaneously in highlands (Doody 2009. Q. Rev. Biol. 84:229–252; Magnusson and Lima 1984. J. Herpetol.18:73–75; Radder and Shine 2007. J. Anim. Ecol.76: 881–887). Communal oviposition in reptiles might result from scarcity of nest-sites offering suitable incubation conditions (direct fitness benefits accruing from the proximity of other eggs) (Doody, *op. cit*; Radder and Shine, *op. cit.*). The reproductive ecology of highland Colombian lizards is poorly known and information on nests, laying, hatching, and hatchlings is not available; thus, this report provides the first data concerning highland lizard communal nesting in Colombia.

FIG. 1. Eggs at different stages of development and one newly hatched young of *Anadia bogotensis* observed at a communal oviposition site under rocks in Colombia.

***ANOLIS CAROLINENSIS* (Green Anole). FEEDING BEHAVIOR.** *Anolis carolinensis* is an animal that feeds largely on small insects, spiders, and other arthropods (Losos 2009. Lizards in an Evolutionary Tree. Univ. California Press, Berkley, California. 507 pp.). At ca. 1215 h on 5 Sept 2006 I observed a Green Anole exhibiting a novel feeding behavior in an area of the Tuskegee National Forest in Macon Co., Alabama, USA. On first observation the animal appeared to be trapped in a spider's web, but upon further investigation, it was discovered that the animal had intentionally moved out onto the web in order to feed upon the resident spider. The anole remained on the web while it consumed its prey, then moved off the web, onto the adjacent branch, and out of sight. To my knowledge there have been no previously reported instances of a Green Anole demonstrating this type of feeding behavior, which seems to imply that this could be a hunting strategy for this species that is rarely observed.

FIG. 1. *Anolis carolinensis* feeding on a spider by having moved out onto its web.

DAVID BROTHERS, Department of Herpetology, Zoo Atlanta, 800 Cherokee Ave SE Atlanta, Georgia 30315, USA; e-mail: dbrothers@zooatlanta.org.

***ANOLIS OXYLOPHUS* (Stream Anole). PECCARY WALLOWS AS NOVEL HABITAT.** Over the course of two months (June–July 2012), we surveyed six water-filled Collared Peccary (*Pecari tajacu*) wallows (places where peccaries roll that later fill with water) at La Selva Biological Station, Heredia, Costa Rica. All wallows were used by peccaries during the time of our surveys, as evidenced by fresh tracks and hair imprints in the mud. At two of the wallows, we noted the presence of *Anolis oxylophus*, which we identified using Savage (2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). At wallow #1, one *A. oxylophus* was positioned on a piece of submerged debris directly in the water. At wallow #2, one *A. oxylophus* was located on leaf litter under a small branch, approximately 0.5 m away from the wallow itself. Both *A. oxylophus* were stationary and were observed at midday. Wallow #1 has an

area of approximately 1.5 m^2 (assuming an elliptical shape) and is around 150 m from the nearest stream, while wallow #2 has an approximate area of 3.4 m^2 and is about 50 m away from the nearest stream. In September 2012 we revisited both wallows and found a subadult female *A. oxylophus* (SVL: 56.1 mm) in standing water at wallow #2. Wallow #1 no longer contained water.

Historically, *A. oxylophus* has been observed living in and very close to streams, and has not been observed beyond the riparian zone (Savage 2002, *op. cit.*; Vitt et al 1995. Can. J. Zool. 73:1918–1927). To our knowledge, our observations are the first of *A. oxylophus* using peccary wallows. Our observations suggest that these tropical anoles are able to utilize a wider range of habitats than has previously been reported, which may have important implications for conservation efforts. In the Amazon, White-lipped Peccaries (*Tayassu pecari*) have been recognized as ecosystem engineers because of their habit of maintaining wallows, which amphibians use as reproductive habitat (Beck et al. 2010. J. Trop. Ecol. 26:407–414; Zimmerman and Bierregaard 1986. J. Biogeog. 13:133–143). Some Central American amphibian species have recently been observed using Collared Peccary wallows for breeding (Reider and Ream, ms. in review). The presence of *A. oxylophus* in and around Collared Peccary wallows indicates that wallows might be important, albeit temporary, habitat for aquatic reptiles in addition to amphibians. Our observations might imply that wallows serve as important stops for *A. oxylophus* moving between streams and warrant additional research to investigate the dispersal patterns of this species. Additionally, future studies of the biology of *A. oxylophus* should consider that some individuals might be spending a portion of their time away from streams.

We thank the staff at La Selva Biological Station for logistical support. These observations were made possible by funds from the Organization for Tropical Studies and the National Science Foundation Research Experience for Undergraduates program.

***ANOLIS SAGREI* (Brown Anole). NEST-SITE CHOICE.** *Anolis sagrei* is native to Cuba and the Bahamas, and has been introduced throughout many tropical and subtropical regions of the world (Kolbe et al. 2004. Nature 431:177–181). Although *A. sagrei* has served as a model for many ecological and behavioral studies (Losos 2009. Lizards in an Evolutionary Tree: Ecology and Adaptive Radiation of Anoles. Univ. of California Press. 528 pp.), relatively little is known about its oviposition behavior. Like all anoles, female *A. sagrei* produce a single egg clutch, for the duration of a breeding season lasting from April to October (Lee et al. 1989. Copeia 1989:930–937). Despite their frequent egg production, the lack of published information about their oviposition sites is largely attributable to difficulty in finding nests.

During field work from 29 September to 9 October 2012, we documented five *Anolis* eggs on two spoil islands in the intracoastal waterway near Marineland, Florida, USA (29.640042°N, 81.214419°W; WGS 84). All eggs were found in soil beneath wooden cover objects. On two occasions, two eggs were found under the same cover object (four eggs total). The fifth egg was found under a board that also contained hundreds of individuals of an unknown ant species. Two of the eggs (found under the same object) were empty shells that hatched earlier, desiccated, or were depredated; the other three eggs were intact and turgid (including the egg in the presence of ants). However, one of the intact eggs had disappeared less than one hour after discovery, possibly depredated upon by a fiddler crab at the study site (*Uca* sp.). Given the high densities of *A. sagrei*, it is unlikely that these eggs belonged to another lizard species (e.g., *Anolis carolinensis*, the only other lizard on these islands, which occurs at relatively low densities).

To assess microhabitat characteristics of the oviposition sites, we took soil samples to measure moisture content and hemisperhical photos to measure canopy openness (methodology of Doody et al. 2006. Herpetol. Rev. 37:49–52) at each oviposition site. The three intact eggs were in soil that had an average moisture content of 15.8% (range 15.0–16.5%), whereas the soil moisture content around the non-intact eggs was 63.0%. The intact eggs were found at relatively open sites (mean canopy openness = 46.7%, range: 43.7–51.2%) compared to the site with the non-intact eggs (14.8% canopy openness). Canopy openness from these five nests (mean = 33.8%) did not differ from canopy openness measured at 40 randomly selected locations on the islands (mean=34.9%), suggesting that female *A. sagrei* choose oviposition sites randomly with respect to canopy cover.

Although nest-site information has been reported for other *Anolis* species (Andrews 1988. Oecologia 76:376–382; Rand 1967. Herpetologica 23:227–230), we are not aware of previously published information for *A. sagrei* in the field. Laboratory-based studies have shown that females select relatively moist conditions that enhance egg hatching success and offspring survival (Reedy et al. 2013. Behav. Ecol. 24:39–46). Although we do not know what moisture conditions were present at the time of ovipostion for the eggs reported here, we nonetheless provide some baseline data on moisture levels that eggs experience in the field. Our small sample suggests that female nest-site choice is not based on canopy cover—a finding that contrasts with other studies of reptiles (e.g., Angilletta et al. 2009. Ecology 90:2933–2939; Warner and Shine 2008. Anim. Behav. 75:861–870), and hence warrants focused studies on nest-site choice and egg ecology in *Anolis sagrei*.

***ASPIDOSCELIS LAREDOENSIS* × *ASPIDOSCELIS GULARIS* (Laredo Striped Whiptail × Texas Spotted Whiptail). HYBRID GYNANDROMORPH.** We evaluate the identity and reproductive status of a whiptail lizard from a site of syntopy involving diploid hybrid-derived parthenogenetic *Aspidoscelis laredoensis* and its maternal progenitor *A. gularis* (Bickham et al. 1976. Herpetologica 32:395–399; McKinney et al. 1973. Herpetologica 29:361–366; Wright et al. 1983. Herpetologica 39:410–416) situated in Texas (Walker 1987. Texas J. Sci. 39:313–334). The specimen is unlike any other in color pattern among a combined total of >1000 specimens of these species examined by us between 1984–2009 from México and Texas. Consequently, it was hypothesized to be

a putative hybrid (i.e., via fertilization of an unreduced diploid egg [2n = 46] of *A. laredoensis* clonal complex A by a reduced sperm [1n = 23] of *A. gularis*) by Walker et al. (1989a. J. Herpetol. 23:119–130). We have subsequently examined several live/freshly killed male and female putative hybrids of *A. laredoensis* × *A. gularis* from Texas and Mexico that were subjected to confirmational studies of their genealogies based on triploidy as verified by karyotypes (Walker et al. 1989a, *op. cit.*; Walker et al. 1989b. Copeia 1989:1059–1064) and skin histocompatibility experiments (Abuhteba et al. 2000. Can. J. Zool. 78:895–904; Abuhteba et al. 2001. Copeia 2001:262–266). Not surprisingly, morphological studies of these hybrids have also revealed the presence of dorsal and ventral color pattern, scutellation, and meristic variables that differ from the parental species. Herein, we use morphological characters and a detailed description of color pattern in support of our identification of a female hybrid deposited in the Arkansas State University Museum of Zoology (ASUMZ). The genealogical status of the animal is also correlated with an aberrant histological condition of reproductive organs that we describe.

We made seven visits to the rural community of Artesia Wells (28.281274°N, 99.285796°W) in La Salle Co., Texas, USA, to collect and observe *A. laredoensis* and *A. gularis* in mesquite-invaded, overgrazed, and degraded sandy habitat along unpaved roads, and in adjacent pastures and fields near jct Texas 133-135 located west of Interstate 35 and railroad tracks. This is one of only three known sites for *A. laredoensis* well-removed from the Rio Grande in La Salle and Dimmit counties, whereas *A. gularis* is

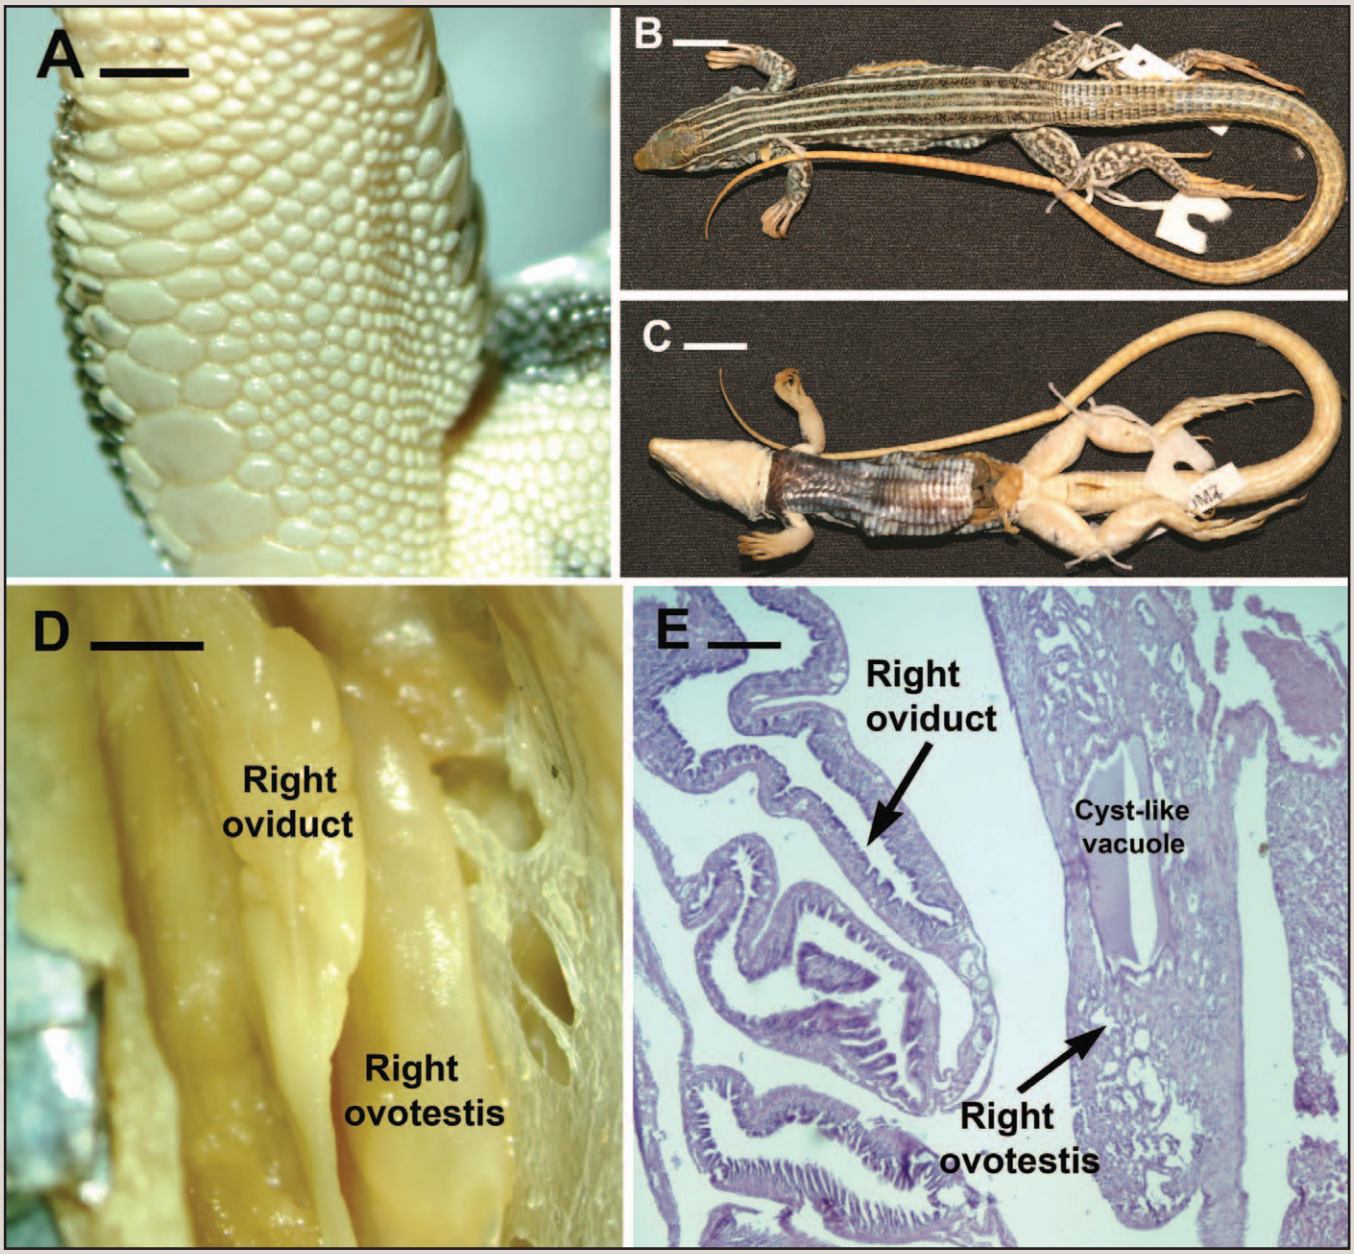

FIG. 1. Morphological characteristics of a hybrid gynandromorph of *Aspidoscelis laredoensis* × *Aspidoscelis gularis* (ASUMZ 6250) collected from Artesia Wells, La Salle Co., Texas, USA. A) Postantebrachial scales of right antebrachium; line = 1 mm. B) Dorsal coloration and pattern; line = 10 mm for B and C. C) Ventral coloration. D) Right gonadal structures; line = 1 mm. E) Longitudinal histosection of right oviduct and ovotestis; line = 100 µm.

widely distributed in both of them (Walker et al. (2004. Texas J. Sci. 56:237–252). We collected 21 (51.2%) parthenogenetic *A. laredoensis* [26 April 1986 (UADZ 1438–1440, N = 3); 16 July 1986 (UADZ 19511–1953, N = 3); 7 September 1996 (UADZ 5764–5769, N = 6); 8 September 1996 (UADZ 5771, 5772, 5774–5776, N = 5); 31 August 1997 (UADZ 5982–5985; N = 4)], 18 (43.9%) gonochoristic *A. gularis* [26 April 1986 (UADZ 1630–1634, N = 5); 2 May 1986 (UADZ 1626–1629, N = 4); 16 July 1986 (UADZ 1998, 1999, N = 2); 19 May 1989 (UADZ 3548, 3549, N = 2); 7 September 1996 (UADZ 5761–5763, N = 3); 8 September 1996 (N = UADZ 5770, 5773; N = 2)], and two (4.8%) hybrids of *A. laredoensis* × *A. gularis* [25 April 1986 (UADZ 1626, N = 1 male); 16 July 1986 (UADZ 2017, N = 1 putative female).

The large distinctively patterned hybrid, UADZ 2017, became ASUMZ 6250 in preparation for this study. It has a SVL of 88 mm, head length of 26.5 mm, head width of 13.0 mm, and body mass obtained before preservation of 14.0 g. It is 9% and 21.5% larger in SVL and body mass, respectively, than the largest parthenogen from Artesia Wells (e.g., mean 69.3 ± 2.75; range 61–80 mm SVL, N = 12) collected on various dates. The large size of ASUMZ 6250 apparently stemmed from hybrid vigor in what externally appeared to be a female of *A. laredoensis* × *A. gularis*. Its postantebrachial scales (Fig. 1A) are intermediate between the moderately enlarged scales of *A. laredoensis* and the enlarged and plate-like scales of *A. gularis*, though being more like the latter. Similarly, the score for one meristic character in ASUMZ 6250 (first number presented in the following list) is below (1), one is above (5), and three (2, 3, 4) are within the ranges of variation for the other specimens of *A. laredoensis* from Artesia Wells (mean, range, N): 1): granular scales around midbody, 83 (91.6 ± 0.54, 88–97, N = 17); 2) granular scales from occiput to base of tail, 226 (227.8 ± 1.00, 221–239, N = 17), 3) granular scales between the paravertebral stripes, 9 (11.1 ± 0.28, 9–14, N =17); 4) right and left femoral pores summed, 36 (32.6 ± 0.33, 30–36, N = 17); and 5) right and left circumorbital scale series summed, 15 (10.3 ± 0.31, 8–12, N = 16).

In life, ASUMZ 6250 possessed a distinctive combination of ornate color pattern attributes that we have never observed in another female from either a site of allopatry or syntopy involving *A. laredoensis* and/or *A. gularis*. This individual of *A. laredoensis* × *A. gularis* (notes made prior to preservation) has a dorsal pattern more similar to *A. laredoensis* and a ventral pattern more similar to *A. gularis*. The dorsal pattern consisted of three pairs of moderately (lateral) to well-defined (dorsolateral and paravertebral) primary stripes and a single vertebral (traits of *A. laredoensis*; Fig. 1B). In life, the green-gray-white lateral and green-yellow dorsolateral and paravertebral stripes were positioned between green-brown-black fields; the stripes ended near the tail. Using the left side of the body for analysis, we noted nine gray-white vertical bars in the lower lateral field, and 19 distinct rounded gray-white spots in the upper lateral field. Some of the spots and bars of the upper and lower lateral fields, respectively, were fused to or superimposed upon the lateral stripes (Fig. 1B). The tail was olive-tan. The upper parts of forelimbs were brown with cream-white streaks. The hindlimbs were brown with gray to yellow spots/reticulations (Fig. 1B). Also included was a pink-red throat and mesoptychium (the latter with a pale purple suffusion), purple-black thoracic region, purple-blue abdominal region (scales with darker edges), cream-white thighs and femora, and cream-white-pink tail (Fig. 1C).

We used standard histological techniques to prepare reproductive tissues for light microscopy. Gonadal tissues were dehydrated in a graded series of ethanol, cleared in xylene, embedded in paraffin, sectioned with a rotary microtome into 10 µm serial sections, stained with Harris hematoxylin and counterstained with eosin.

The genital anatomy of ASUMZ 6250 differed markedly from that found in a gynandromorph *A. laredoensis* (ASUMZ 4654) collected in Reynosa, Tamaulipas, Mexico (Trauth et al. 2013. Herpetol. Rev. 44:138–140). However, as in ASUMZ 4654, a pair of small regressed oviducts was observed lying laterally to equally small, oblong gonadal masses (Fig. 1D). The gonadal morphologies were unrecognizable macroscopically as ovaries; these gonads appeared slightly orange in coloration upon gross inspection. The right gonadal mass and oviduct were examined histologically revealing a multipart anatomy including adrenal tissue, mesonephric duct and tubules, and rudimentary ovotestis along side of convoluted, regressed oviducts. The mesonephric tubules and duct were associated with the adrenal tissue. The ovotestis mass exhibited numerous regressed seminiferous tubules along its entire length. These tubules averaged 41.8 µm (range 30.0–55.0 µm; N = 10) in diameter. No recognizable primordial follicles were observed within the ovotestis. A large translucent, oblong, cyst-like vacuole (follicle?) dominated most of the distal ovotestis, a small segment of which is shown in Fig. 1E. This structure exhibited no distinguishing features characteristic of secondary or tertiary follicles, but appeared to retain a poorly-developed granulosa cell layer and some scattered ooplasm. The glandular middle region of the oviduct averaged 73.5 µm (range 54.8–90.3 µm; N = 10) in height and exhibited regressed tubuloalveolar uterine glands (Fig. 1E) that averaged 27.5 µm (range 22.6–36.1 µm; N = 10) at their greatest diameter. The surface mucosa of the glandular region was strongly basophilic.

This is only the third publication known to us in which gynandromorphism has been described in specimens of whiptail lizard. Mitchell and Fouquette (1978. Copeia 1978:156–159) discovered an adult individual of *Cnemidophorus inornatus arizonae* (= *Aspidoscelis inornata arizonae* sensu Reeder et al. 2002. 3365:1–61) from 7 km SE of Willcox, Cochise Co., Arizona, with male reproductive organs in the left side of the body cavity and female organs in the right side of the cavity. These authors, based on morphology, rejected the possibility that the specimen in question was a hybrid involving triploid *A. uniparens*, which was also present at the Arizona site. Cole et al. (2010. Am. Mus. Novitat. 3698:1–43) used the terminology "apparently female (but intersex) laboratory hybrid" to describe a genetically confirmed individual of *A. inornata arizonae* (♀) × *A. tigris marmorata* (♂). Lastly, we reported a gynandromorph of *A. laredoensis* in this journal (Trauth et al. 2013, *op. cit.*).

base this statement on reports of multiple hybrids from New Mexico of *A. tesselata* × *A. tigris* (Taylor et al. 2001. Am. Mus. Novitat. 3345:1–64), *A. neomexicana* × *A. inornata* (Taylor and Walker 1996. Copeia 1996:945–954), and *A. neomexicana* × *A. sexlineata* (Manning et al. 2005. Am. Mus. Novitat. 3492:1–56), and hybrids from Texas of *A. laredoensis* × *A. gularis* (Walker et al. 1989a. J. Herpetol. 23:119–130). We evaluate the identity and reproductive status of two male whiptail lizards in the Arkansas State University Museum of Zoology from two sites of syntopy in Texas (Walker 1987. Texas J. Sci. 39:313–334) between *A. laredoensis* and its maternal progenitor *A. gularis* (McKinney et al. 1973. Herpetologica 29:361–366; Bickham et al. 1976. Herpetologica 32:395–399; Wright et al. 1983. Herpetologica 39:410–416). Included are ASUMZ 31263 collected 17 July 1983 from 1.6 km S of Laredo and E of U.S. Hwy 83, Webb Co., and ASUMZ 31264 collected 2 May 1986 from Artesia Wells, La Salle Co. In both specimens, details of dorsal and ventral color pattern are in agreement with characters of confirmed hybrids of *A. laredoensis* × *A. gularis* based on a triploid karyotype (Walker et al. 1989b. Copeia 1989:1059–1064) and histocompatibility reactions (Abuteba et al. 2000. Can. J. Zool. 78:895–904; Abuhteba et al. 2001. Copeia 2001:262–266). We also correlate the genealogical status of each animal with the first detailed histological analyses of spermatogenesis and associated reproductive structures in *A. laredoensis* × *A. gularis*, which extends the preliminary treatment of Walker et al. (2008. Herpetol. Rev. 39:340).

Neither ASUMZ 31263 (67 mm SVL, Fig. 1A–B) nor 31264 (69 mm SVL; Fig. 1C–D) could be field identified as adult males of *A. gularis*, as both possessed dorsal patterns and colors similar to *A. laredoensis*. Moreover, each of them lacked the distinctive peach-pink-red throat, intense purple/almost black thorax, and checkered abdomen which characterize adult males of *A. gularis*. In addition, we deemed the size of the postantebrachial scales to be intermediate between the parental species and indicative of hybridity.

We used standard histological methods to prepare reproductive tissues for light microscopy. Gonadal tissues were dehydrated in a graded series of ethanol, cleared in xylene, embedded in paraffin, sectioned with a rotary microtome into 10 µm serial sections, stained with Harris hematoxylin and counterstained with eosin.

ASUMZ 31263 and 31264 possessed well-developed testes, predisposing them as males (Fig. 2A and C). No female genital structures were observed. Histological examination of the right testis, attached epididymis and ductus deferens, and the sexual segment of the right kidney (SSK) indicated that these lizards were at or near the peak of spermatogenic activity. The seminiferous tubules of the testes of both specimens were characterized by a tall seminiferous epithelium 7–9 cell layers in thickness, and they contained what appeared to be functional sperm within expanded lumina. The testis of ASUMZ 31263 measured 4.2 × 2.5 mm, whereas the testis of ASUMZ 31264 measured 6.1 × 3.0 mm. The average diameter of the seminiferous tubules of ASUMZ 31263 and ASUMZ 31264 was 132.3 µm (range 120.7–146.7 µm; N = 10) and 170.8 µm (range 141.3–196.8 µm; N = 10), respectively.

Sperm and cellular debris were observed within the epididymal ducts of both males. The average diameter of the ductus deferens of ASUMZ 31263 and ASUMZ 31264 (Fig. 2B and D) in ductal segments adjacent to their respective kidneys was 140.2 µm (range 124.0–168.0 µm; N = 10) and 145.0 µm (range 120.6–193.5 µm; N = 10). The SSK of the kidneys (Fig. 2B) were great hypertrophied and acidophilic in these individuals. These tubules averaged 109.9 µm (range 96.0–128.0 µm; N = 10) in ASUMZ 31263 and 102.6 µm (range 88.0–126.4 µm; N = 10) in ASUMZ 31264.

Hybrid males of *A. laredoensis* × *A. gularis* are known to be triploid 3n = ~69 (Walker et al. 1989b, *op. cit.*), with XXY sex chromosomes (sensu Cole et al. 1969. Am. Mus. Novitat. 2395:1–14) based on two genomes from *A. gularis* and one from *A. sexlineata* via two hybridizations (Walker et al. 1989b, *op. cit.*). This would seem to preclude meiotic development of genetically capable haploid sperm, a condition also inferred from histological sections from 12 males of *A. tesselata* × *A. tigris* (Taylor et al. 2001. Am. Mus. Novitat. 3345:1–64). However, assuming that adult hybrid males engage in mating behaviors, and even inseminations of females of *A. laredoensis* and *A. gularis*, there is no evidence that the existence of such rogue individuals is destabilizing to the reproductive success in either species.

WALKER**, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701, USA (e-mail: jmwalker@uark.edu); **JAMES E. CORDES**, Division of Sciences and Mathematics, Louisiana State University Eunice, Eunice, Louisiana 70535, USA (e-mail: jcordes@lsue.edu).

***ASPIDOSCELIS NEOMEXICANA* (New Mexico Whiptail). HABITAT.** The main distribution area of diploid parthenogenetic *Aspidoscelis neomexicana* (= *Cnemidophorus neomexicanus*) encompasses areas essentially contiguous with the Rio Grande entrenchment from northern New Mexico to El Paso, Texas (Axtell 1966. Herpetologica 22:241–253). Although New Mexico Whiptail is abundant in parts of the city of El Paso (Cordes et al.1989. Texas J. Sci. 41:425–428), it has not been reported from south of the river in Ciudad Juárez, Chihuahua, or elsewhere in México (Cordes and Walker 2009. Southwest. Nat. 54:226–230). Subsequent to Axtell's (1966, *op. cit.*) analysis of the geographic distribution of *A. neomexicana*, arrays of the species widely disjunct from the main distribution area have been reported as follows from New Mexico: Hidalgo Co. at sites northwest of Lordsburg (Cole et al 1988. Amer. Mus. Novitat. 2905:1–38); San Miguel Co. at Conchas Lake (Leuck et al. 1981. Southwest. Nat. 26:72–74; Manning et al. 2005. Amer. Mus. Novitat. 3492:1–56; Walker et al. 1992. Southwest. Nat. 37:82–86); De Baca Co. at Fort Sumner (Manning et al., *op. cit.*; Manning and Walker 2006. Amer. Midl. Nat. 155:411–416; Taylor 2002. Herpetol. Rev. 33:223–224); Lincoln Co. southwest of Carrizozo (Burkett et al. 2004. Herpetol. Rev. 35:408), and Roosevelt Co. in the extreme western part (Cordes and Walker 2011. Herpetol. Rev. 42:568). The species also has been reported from Arizona in Apache Co. in Petrified Forest National Park (Persons and Wright 1999. Herpetol. Rev. 30:207–209). It has been reported from Utah in Salt Lake Co. in Salt Lake City and Sandy City and from Utah Co. in Lehi (Oliver and Wright 2007. Western North Amer. Nat. 67:461–467). Finally, it has been reported from Texas in El Paso and Hudspeth counties in the vicinity of Hueco Tanks and Horizon Lake (Cordes et al., *op. cit.*) and in Presidio Co. south of Candelaria (Cordes et al., *op. cit.*; Cordes and Walker, *op. cit.*). We agree that the Utah and Arizona records for *A. neomexicana* are most likely based on the descendants of lizards introduced by humans (Oliver and Wright, *op. cit.*; Persons and Wright, *op. cit.*). We do not concur with these authors that the apparently disjunct groups of *A. neomexicana* in New Mexico and Texas have resulted from human introductions (for reviews see Taylor, *op. cit.*; Manning et al., *op. cit.*; Cordes and Walker, *op. cit.*).

In Texas, locality records for *A. neomexicana* are clustered in the El Paso metropolitan area, ca. 70 km NE of the city in the vicinities of Hueco Tanks State Park and Horizon Lake, El Paso and Hudspeth counties, and 200 km SE of the city at south of Candelaria, Presidio Co. Two of us have recently detailed aspects of the distributional ecology for the species and its congeners south of Candelaria (Cordes and Walker, *op. cit.*). We present observations on the habitats utilized by *A. neomexicana* in the Hueco Tanks-Horizon Lake area of El Paso and Hudspeth counties, the only records for the species well removed from the Rio Grande in Texas. The presence of *A. neomexicana* in this bi-county area is vouchered by these specimens examined from the Sul Ross State University (SRSU) and University of Texas at El Paso (UTEP) herpetology collections, and pitfall trap records: El Paso Co.: Hueco Mountains of Fort Bliss (pitfall trapped/released by DWB), 31.913952°N, 106.152937°W, WGS84; Hueco Tanks State Park (UTEP 609, 10793, 10794, N = 3); Hueco Tanks on south side of first enclave or rocks east of entrance (UTEP 1695, 1696, N = 2); Horizon Lake on west bank (SRSU 4162, 4195, N = 2); Hueco Mountains between Horizon Lake and El Paso National Compressor Station (SRSU 4156, 4161, N = 2); Hudspeth Co.: between Horizon Lake and El Paso National Compressor Station (SRSU 4185, 4186, N = 2).

The non-riverine occurrence of *A. neomexicana* in El Paso Co. is in the Hueco Bolson (i.e., a flat valley that drains to a central evaporation pan or playa) of the Chihuahuan Desert near Horizon Lake. This bolson is characterized by a substratum of sandy to gravelly soil that has accumulated since Miocene time. During the Pleistocene the bolson was flooded by Lake Cabeza de Vaca, a huge body of water that extended southeasterly deep into Chihuahua, México, northward into central New Mexico, and westward to the Sierra Madre Occidental in Sonora, México (Axtell 1977. *In* R. H. Wauer and D. H. Riskind [eds.], Transactions of the Symposium on the Biological Resources of the Chihuahuan Desert Region, United States and Mexico, pp. 493–512. U.S. Department of the Interior, National Park Service Transactions and Proceedings Series no. 3). Today, the edges of the Hueco Bolson contain gravel grading into alluvium and larger rock-debris from the Franklin Mountains to the west and the Hueco Mountains to the east as aggradations of the mountains and filling of the bolson continues.

Horizon Lake, now known as Shadow Mountain Lake, is a man-made impoundment created by the Horizon Corporation as a part of their development plan for the area. The soil in the area where the lake was created is aeolian sands overlaying the slope of an eroded karst which projects slightly above the bolson floor only a short distance to the west of the lake. Vegetation in the immediate vicinity consists of Sand Sagebrush (*Artemisia filifolia*), Spike Dropseed (*Sporobolus contractus*), and Broom Snakeweed (*Xanthocephalum sarothrae*); these are interspersed with Soaptree Yucca (*Yucca elata*) and Honey Mesquite (*Prosopis glandulosa*). The aeolian sands tend to accumulate at the bases of the mesquite and yucca clusters creating hummocks with blow-out open spaces nearby. Numerous small burrows were evident at the bases of the hummocks, and to a lesser extent, within

the open spaces. Species of lizards in addition to *A. neomexicana* at this locality were *Aspidoscelis marmorata* (= *C. tigris marmoratus*; Marbled Whiptail) and *Uta stansburiana* (Common Side-blotched Lizard).

The habitat for *A. neomexicana* at Horizon Lake was similar to the habitat for the species near Hueco Tanks State Park where the species was abundant. However, specimens of *A. neomexicana* collected from Hudspeth Co. only a few miles to the east of Horizon Lake were on bajada slopes of the Hueco Mountains with a gravelly to rocky substrate. Dominant plants here were Creosote Bush (*Larrea tridentata*), Fluff Grass (*Erioneuron pulchellum*), Viscid Acacia (*Acacia neovernicosa*), Prickly Pear (*Opuntia* sp.), Lechuguilla (*Agave lechuguilla*), and some Torrey Yucca (*Yucca torreyi*). Associated lizards at this locality in addition to *A. neomexicana* were *Aspidoscelis exsanguis* (Chihuahuan Spotted Whiptail), *Aspidoscelis inornata* (Little Striped Whiptail), *Cophosaurus texanus* (Greater Earless Lizard), and *Phynosoma modestum* (Round-tailed Horned Lizard). For collections via pitfall/drift fence trapping along the Hueco Mountain foot slopes and drainages, *Coleonyx brevis* (Texas Banded Gecko) was one of the most prominent lizard species present.

The occupation of both playa and outwash habitats by *A. neomexicana* in the areas of El Paso and Hudspeth counties well removed from the Rio Grande fits in perfectly with Axtell's (1966, *op. cit.*) description of the fidelity to playa habitats of the species in the southern portion of its range. The syntopy of *A. neomexicana* with other congeners at these sites also corroborates Axtell's discussion.

We thank Texas Parks and Wildlife Department for permission granted to JEC and DAB to collect specimens of *A. neomexicana* in Texas. Much of the descriptions of habitats for *A. neomexicana* presented herein were contributed by JFS.

***ASPIDOSCELIS VELOX* (Plateau Striped Whiptail). BIFURCATION.** *Aspidoscelis velox*, a triploid hybrid-derived parthenogenetic species (Moritz et al. 1989. Evolution 43:958–968), has a natural range extending from the four corners area into contiguous parts of Colorado, New Mexico, Arizona, and Utah, and it has been introduced in Oregon (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed. Houghton Mifflin Co., New York, New York. 533 pp.). In a sample of *A. velox* (= *Cnemidophorus innotatus*, sensu Wright 1993. *In* J. W. Wright and L. J. Vitt [eds.], Biology of Whiptail Lizards, pp. 27–81. Oklahoma Museum of Natural History, Norman, Oklahoma) from 11.5 km N of Kanab and west of US Hwy 89 in the vicinity (37.14726°N, 112.57979°W; 1693 ± 2 m elev.) of Coral Pink Sands State Park, Kane Co., southern central Utah, are two preserved lizards (University of Arkansas Department of Zoology, UADZ 9168 of 87 mm SVL from 26 July 2012 and 9176 of 58 mm SVL from 27 July 2012), each with a with a caudal bifurcation. Unlike the very small representation of one branch of this anomaly in a specimen of *Ameiva ameiva* reported by Gogliath et al. (2012. Herpetol. Rev. 43:128–129), both individuals of *A. velox* have conspicuously developed bifurcations. In the large third or fourth year adult

FIG. 1. Noteworthy specimens of *Aspidoscelis velox* (= *Cnemidophorus innotatus* [sensu Wright *op. cit.*]) from Kane Co., Utah: UADZ 9168 (adult of 87 mm SVL) with short distorted original and supernumerary branches distal to bifurcation of the tail; UADZ 9176 (subadult of 58 mm SVL) with elongated original (63 mm) and supernumerary (57 mm) branches distal to bifurcation of the tail. During collection, the tail of each lizard was inadvertently broken, following which a small section was removed from each for DNA extraction.

(UADZ 9168), the supernumerary branch is ~ 29 mm in length; however, the original tail retains evidence of the initiating injury, being ~ 11 mm from bifurcation to a rigid angle indicating damaged/healed vertebrae, ~ 15 mm to a semi-rigid angle, and ~ 6 mm to the tip. The second year juvenile lizard (UADZ 9176) presents an amazing example of "twin" tails (Fig. 1). The original tail, as indicated by position and scalation, is 63 mm in length from the bifurcation; the supernumerary branch is 57 mm in length. We surmise that the bifid tail in the adult would have been inconsequential to its biology, whereas the amount of energy diverted into the growth and maintenance of the structure in the juvenile could have affected its reproductive potential. These are the only specimens of *A. velox* with bifid tails among >200 specimen of the species that we have examined from Arizona, New Mexico, and Utah.

We are grateful to the Utah Division of Wildlife Resources for issuing a license to JEC for collection of *A. velox* in Kane Co., Utah. The 2012 expedition to Utah and New Mexico was partially funded by an Endowed Professorship awarded to JEC by Louisiana State University Eunice and Opelousas General Hospital.

JAMES E. CORDES, Division of Sciences and Mathematics, Louisiana State University Eunice, Eunice, Louisiana 70535, USA (e-mail: jcordes@lsue.edu); **JAMES M. WALKER**, Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701, USA (e-mail: jmwalker@uark.edu).

***BRONCHOCELA CRISTATELLA* (Crested Green Lizard). ATTEMPTED PREY.** *Bronchocela cristatella* is a familiar agamid lizard in Southeast Asia, frequenting a variety of disturbed and pristine habitats, and especially common in open areas, such as parks and gardens, its diet is reported to be comprised mayflies, beetles, flies, and ants, in addition to skinks (Das 2010. A Field Guide to the Reptiles of South-east Asia. New Holland Publishers [UK], Ltd., London. 376 pp.; Diong and Lim 1998. Raffles Bull. Zool. 46:345–359).

On 21 October 2012, at 1128 h, an adult (ca. 110 mm SVL) male *Bronchocela cristatella* was observed at a patch of beach forest, adjacent to a mangrove creek at Teluk Penyuk (1.755833°N, 110.320278°E, ca. 56 m elev.), at the foothills of Gunung Santubong, Sarawak, East Malaysia (Borneo). It had gripped the

FIG. 1. *Bronchocela cristatella* with the posterior end of a *Lonchodes jejunus* (Phasmatida, Heteronemiidae, Lonchodinae).

posterior 5 mm of the abdomen of a ca. 130 mm long phasmid (or stick insect), *Lonchodes jejunus* (Phasmatida, Heteronemiidae, Lonchodinae) in its mouth (Fig. 1). For ca. eight minutes, the lizard struggled to subdue the stick insect, and finally released its hold, and moved back to the shrub vegetation at the edge of the beach, leaving the now nearly immobile insect. Still and video images were taken with a Sony HDR-XR 350E camera; these and additional still and video images have been registered with the Raffles Museum of Biodiversity Research, National University of Singapore (ZRC [IMG] 2.176a–c).

The phasmid genus *Lonchodes* includes long-bodied and slender species of uniform thickness; females may have anteriorly swollen mesonotum. Bragg (2001. Phasmids of Borneo. Natural History Publications [Borneo] Sdn Bhd., Kota Kinabalu. xi + 772 pp.) listed at least five species within the genus from Santubong and adjacent regions of western Sarawak, of the 19 species known from Borneo (excluding two additional species erroneously recorded from the island). Phasmids have earlier been reported in saurian diets, although chiefly of the much larger varanids (e.g., Pianka 1970. West. Aust. Natural. 11:141–144; Greene 1986. Fieldiana Zool., n.s. [31]:i–iii; 1–12), and no Asian agamids have been reported to consume or attempt to predate on these large-growing insects.

I thank Francis Seow-Choen and Chan Chew Lun for identification of the phasmid, and Kelvin K. P. Lim for the ZRC voucher numbers. The Sarawak Forest Department issued a research permit (No. NCCD.907.4.4 Jld.7–39) and the Fundamental Research Grant, number FRGS/07(04)787/2010(68), Ministry of Higher Education supported research on the herpetofauna of Sarawak.

INDRANEIL DAS, Institute of Biodiversity and Environmental Conservation, Universiti Malaysia, 94300 Kota Samarahan, Sarawak, Malaysia; e-mail: idas@ibec.unimas.my.

***CERCOSAURA SCHREIBERSII* (Long-tailed Little Lizard). DEFENSIVE BEHAVIOR.** Little is known about the natural history of *Cercosaura schreibersii*, a small gymnophthalmid lizard (Tedesco and Céspedez 2005. Bol. Asoc. Esp. Herpetol. 16:30–32). The few available data are related to taxonomic features (Cei 1993. Mus. Reg. Sci. Nat., Torino, Monogr. 14, 949 pp.; Doan 2003. Zool. J. Linn. Soc. 137:101–115; Tedesco and Cei 1999. Boll. Mus. Reg. Sci. Nat. 16:309–320) or reproductive mechanisms (Balestrini et al. 2010. Biota Neotrop. 10:131–139). Here we provide the first report on death-feigning behavior combined with caudal autotomy in this species.

On 15 July 2012 we collected two *Cercosaura schreibersii* specimens, an adult and a juvenile, under a log in putrefaction in a xeric grassland at the Paraje Zapallo (27.845028°S, 57.866842°W), San Luis del Palmar Department, Corrientes province, Argentina. The adult specimen (total length = 80.58 mm) responded aggressively by biting the collectors' fingers upon initial attempt to lift it for examination. The lizard was put down and at which time it leaned backwards and began to rotate in a circular motion over its own body, causing autotomy of its tail. After this it placed its forelimbs stretched over the abdomen and arched its body and head back. It remained motionless for a couple of minutes, feigning death.

Caudal autotomy is a common method of antidepredatory behavior, reported in squamates, salamanders, and rodents (Arnold 1988. *In* Gans and Huey [eds.], Biology of the Reptilia Vol. 16. Defense and Life History, pp. 235–273. Alan R. Liss, New York; Brito et al. 2001. Herpetol. Rev. 32:43–44). But reports on caudal autotomy in conjunction with death feigning are scarce (Torres-Cervantes et al. 2004. Herpetol. Rev. 35:384). In this case, the animal did not lose its tail via traditional autotomy, rather it twisted its own body in order to detach it.

MARIA ESTHER TEDESCO (e-mail: tikytedesco@yahoo.com.ar), **JUAN MANUEL CÉSPEDEZ, JORGE A. CÉSPEDEZ** (e-mail: cespedez@hotmail.com), and **MAXI ROMERO**, Laboratorio de Herpetología, Facultad de Ciencias Exactas y Naturales y Agrimensura, Universidad Nacional del Nordeste, Campus Universitario Corrientes, Avenida Libertad 5470, CP. 3440, Corrientes, Argentina.

***CHALCIDES OCELLATUS* (Ocellated Skink). SPIDER PREDATION.** The spider genus *Latrodectus* has a worldwide distribution, with many species recorded as having a broad diet and as being occasional predators of lizards and mice (Garb et al. 2004. Mol. Phylog. Evol. 31:1127–1142; e.g., *Latrodectus hasselti* in Knoflach and Van Harten 2001. Fauna of Arabia 19:321–361; *L. pallidus* and *L. revivensis* in Blondheim and Werner 1989. Brit. Herpetol. Soc. Bull. 30:26–27); this is likely the reason for the presence of a vertebrate-specific toxin (-latrotoxin) found in their venom (Garb et al., *op. cit.*). In Europe, the diet of *Latrodectus lilianae* has been found to include the lizards: *Acanthodactylus erythrurus*, *Psammodromus algirus*, *Psammodromus*

PHOTO BY M. COLOMBO

FIG. 1. Female *Latrodectus tredecimguttatus* spider with a dead juvenile *Chalcides ocellatus* in its web; the spider's egg sacks visible in upper left corner.

hispanicus, Tarentola mauritanica (Hòdar and Sànchez-Piñero 2002. J. Zool. Lond. 257:101–109). The only Italian species of *Latrodectus, L. tredecimguttatus,* is reported as occasionally preying on small lizards in Romania (Duma 2006. Travaux du Muséum d'Histoire Naturelle 49:75–81). Schwammer and Baurecht (1988. Herpetozoa 1:73–76) reported predation upon *Podarcis melisellensis* in Croatia.

On 1 August 2011, near Maristella (Sassari province, Sardinia, Italy) while inspecting some black widow spider webs under stones and bushes in a Mediterranean maquis for photographic purposes, a female *L. tredecimguttatus* was observed with a juvenile *Chalcides ocellatus tiligugu* entangled in its web, already dead. The skink clearly bore the bite of the spider on its right side (Fig. 1), showing necrosis of tissues around it. The prey was located under the hunting platform as also observed for *L. lilianae* (Hòdar and Sànchez-Piñero, *op. cit.*) and not in the nest, where at least two egg sacks were present. It is possible that the reptile was either caught while moving under the web, or by falling in it from above, as the web was constructed in a corner of a rocky outcrop covered by *sterpaglie* (extensive growths of Graminaceae). The following day another inspection of the web confirmed that the spider had finished consuming its prey, leaving it on the ground under the web. It is possible, as proposed by Hòdar and Sànchez-Piñero (2002, *op. cit.*) for lizards, that the overlapping of daily activity of both skinks (diurnal) and spiders (nocturnal) in the first hours of the day and at sunset permits this kind of interaction, even more with juvenile skinks that have smaller bodies and better thermoregulation (considering that during summer months this skink's activity is bimodal; Corti et al. 2011. Fauna d'Italia. XLV. Reptilia. Edizioni Calderini, Milan. 270 pp.). In the same area, *L. tredecimguttatus* has been observed preying upon several arthropods but never on vertebrates before (M. Colombo and B. Manunza, pers. obs.); however, predation on reptiles could be more frequent than has been reported, as also stated by Hòdar and Sànchez-Piñero (2002, *op. cit.*). This record represents the first documented case of predation of a spider on a skink in Europe (a not-so-common kind of prey also in other parts of the world; McCormick and Polis 1982. Biol. Rev. Camb. Philos. 57:29–58), and one of the few cases of predation by a spider on a reptile in Italy. This observation adds to the limited knowledge of trophic interactions between reptiles and spiders (an often overlooked phenomenon in food webs; McCormick and Polis, *op. cit.*) in Mediterranean environments, as *C. ocellatus* was already known to feed on arthropods including spiders (Corti et al. 2011, *op. cit.*).

I thank Bruno Manunza and Anna Cataldi for help during searches in the field. I would also like to thank Cesar Ayres, Francesco Ballarin, David Bird, Francesco Ficetola, Iulian Gherghel, Chis-Gleed-Owen, Barbara Knoflach, Bruno Manunza, Nicola Novarini, Stefano Scali, Benedikt Schmidt, Alessio Trotta, and Leonardo Vignoli for sharing useful references and personal observations.

MARCO COLOMBO, via Biancardi 17, 21052 – Busto Arsizio (Varese), Italy; e-mail: oryctes@libero.it.

COPEOGLOSSUM NIGROPUNCTATUM. **ENDOPARASITES.** *Copeoglossum nigropunctatum* occurs in parts of Brazil, French Guiana, Guyana, Venezuela, Isla Margarita, Trinidad, Tobago, Suriname, Bolivia, Peru, and Ecuador (Uetz [ed.] 2012. The Reptile Database. http:www.reptile-database.org. Accessed 1 November 2012). It is the most common skink in Amazonia (Avila-Pires 1995. Zoolog. Verh. Leiden 299:1–706). There are previous reports of nematodes in *C. nigropunctatum* (previously *Mabuya nigropunctata*) from Brazil, *Oochoristica travassosi, Oswaldocruzia* sp., *Physaloptera lutzi, Physaloptera retusa* (Avila and da Silva, 2011. Comp. Parasitol. 78:129–139), *Oochoristica* sp. (Avila et al. 2011. Comp. Parasitol. 78:120–128), *Physalopteroidea venancioi* (de Albuquerque et al. 2012. Comp. Parasitol. 79:64–67) and Peru, *Oswaldocruzia brasiliensis, Parapharyngodon sceleratus, Piratuboides zeae* (McAllister et al. 2010. J. Parasitol. 96:444–447). The purpose of this note is to add to the helminth list of *C. nigropunctatum.*

A sample of 15 *C. nigropunctatum* (mean SVL = 83.3 mm ± 7.9 SD, range = 62–93 mm) collected in Pará State, Brazil in 1995 and 2004, and deposited in the herpetology collection of the Sam Noble Museum (OMNH), Norman Oklahoma, USA as (OMNH 36828–36842, 41807–41811) was examined. Lizards were fixed in 10% formalin and stored in 70% ethanol. The stomachs had previously been removed and were not available for examination. The intestines were removed, opened, and the contents examined under a dissecting microscope. Nematodes were found in the small intestines, prevalence, number infected/number examined × 100 = 73%, mean intensity, mean number helminths = 3.8 ± 2.1 SD, range = 1–7. They were cleared in a drop of lactophenol on a microscope slide, cover slipped, studied under a compound microscope and identified as *Oswaldocruzia vitti.* Voucher nematodes were deposited in the United States National Parasite Collection (USNPC), Beltsville Maryland as USNPC 106130.

We have assigned our specimens to *Oswaldocruzia vitti* because the spicule blade terminates in three bifurcated processes; the spicule blade of *O. brasileinsis* is spatulate. *Oswaldocruzia vitti* was originally described from *Cercosaura eigenmanni* (Brazil) and *C. oshaughnessyi* (Brazil, Ecuador) (Bursey et al. 2004. J. Parasitol. 90:140–145). It was also found in *Alopoglossus angulatus* (Brazil, Ecuador) and *A. atriventris* (Brazil) (Goldberg et al. 2007. Herpetol. J. 17:269–272), *Anolis punctatus* (Brazil, Ecuador) (Goldberg et al. 2006. Amphibia-Reptilia 27:575-579), *Anolis fuscoauratus* (Brazil, Ecuador) (Goldberg et al. 2006. Phyllomedusa 5:83-86), *Arthrosaura reticulata* (Ecuador) (Goldberg et al. 2010. Herpetol. Rev. 41:349-350), *Cercosaura eigenmanni* (Peru) (Bursey et al. 2005. Comp. Parasitol. 72:50-68), *Plica plica* and *P. umbra* (Brazil) (Goldberg et al. 2009. Herpetol. J.19:49-52). *Copeoglossum nigropunctatum* represents a new host record for *Oswaldocruzia vitti.*

We thank Jessa L. Watters (OMNH) for facilitating the loan.

CTENOSAURA HEMILOPHA **(Baja California Spiny-tailed Iguana). DISPERSAL PHENOMENON.** *Ctenosaura hemilopha* is endemic to Baja California Sur, Mexico, including Cerralvo Island located in the Sea of Cortez east of La Paz (Grismer 2002. Amphibians and Reptiles of Baja California including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley. 409 pp.; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed. Houghton Mifflin Co., New York. 560 pp.). This large lizard occurs in arid, sub-tropical scrub habitats where

FIG. 1. *Ctenosaura hemilopha* drifting on log in the Sea of Cortez, Mexico.

most rainfall occurs during late-summer tropical storms. The isolated occurrence of this iguana on the Baja California peninsula presumably results from dispersal over land originating from the Mexican mainland (Smith 1972. Great Basin Nat. 32:104–111) or from human introductions (Stebbins 2003, *op. cit.*). Here we describe a rare observation of a long distance dispersal phenomenon and natural mechanism for dispersal over water.

On 28 September 2012 tropical storm Norman moved northerly over the Sea of Cortez with reports of heavy rain and flooding in La Paz and other coastal towns. While boating on 2 October in the Sea of Cortez between La Paz and Cerralvo Island we observed extensive debris carried by coastal floodwaters and wind. Tree trunks, large branches, and smaller woody debris were observed. The debris field appeared to be moving from the La Paz area toward Cerralvo Island and the open waters of the Sea of Cortez. On the same day an adult *Ctenosaura hemilopha* was found floating on driftwood between La Paz and the northern tip of Cerralvo Island (Fig. 1). The lizard was approximately 7 km W of the island and 40 km E of La Paz (24 km E of the nearest shore). The driftwood log was approximately 90 cm in length and the size of the iguana was estimated at 22 cm SVL. The iguana was captured and appeared to be in good health. It was later released in the village of La Ventana, south of La Paz, Baja California Sur.

Evidently the stranded iguana, caught in flood waters, floated on debris for 24–40 km or more from the La Paz area and for a period of up to four days (i.e., from the time the storm began to the time observed in open water). It is plausible that this lizard could have continued to drift at a rate of 5–10 km/day and reached Cerralvo Island within 1–2 days. Our observation documents a natural dispersal event rarely seen, and indicates that peninsular individuals of this species may still be colonizing the island today.

We thank Pangaro Yoni, La Ventana, Baja California Sur, Mexico.

***CTENOSAURA SIMILIS* (Gray's Spiny-tailed Iguana). NON-NATIVE DIET.** *Ctenosaura similis* is native to Central America, occurring from Mexico through to Panama (Traveset 1990. Am. Midl. Nat. 123:402–404), and has been introduced to several Caribbean islands, and Florida, USA (Kraus 2009. Alien Reptiles and Amphibians: A Scientific Compendium and Analysis. Springer, [Dordrecht, Netherlands], 563 pp.; Krysko et al. 2003. Florida Sci. 66:74-79). This species exhibits an ontogenetic diet shift, where juveniles are primarily carnivorous and adults are primarily herbivorous (Hirth 1963. Ecology 44:613–615; Krysko et al. 2009. Florida Sci. 72:48–58; Rand et al. 1990. J. Herpetol. 24:211–214). Diet has been documented for some introduced populations in southern Florida, particularly those on Gasparilla Island, Charlotte and Lee counties, and Key Biscayne, Miami-Dade Co. (Krysko et al. 2009, *op. cit.*, Krysko et al. 2010. Herpetol. Cons. Biol. 5:132–142). Herein, we augment previously documented diet of *C. similis* on Key Biscayne.

FIG. 1. *Ctenosaura similis* eating *Canavalia rosea* flowers at Crandon Park beach.

On 14 September 2012 between 1205–1220 h, a single adult female *Ctenosaura similis* was observed in beach coastal habitat feeding on flowers of the native Baybean, *Canavalia rosea* (Fabaceae), at Crandon Park, Key Biscayne (25.706°N, 80.153°W, WGS84; elev. <1 m). The iguana periodically foraged through a large area (ca. 20 m x 20 m) of Baybean and ate 21 individual flowers; no other parts of the plant were eaten. This is the first documentation of *C. similis* consuming *Canavalia rosea* (Krysko et al. 2009, *op. cit.*; Krysko et al. 2010, *op. cit.*). Florida currently has the largest number of non-native herpetofaunal species in the world, and the impact of native/non-native interactions on ecosystem functioning remain poorly understood (Krysko et al. 2011. Zootaxa 3028:1–64). The potential impacts of this feeding behavior on local plant survivability are not known and should be considered important in future monitoring. No sympatric reptile species were observed throughout the duration of the feeding behavior.

KRYSKO**, Division of Herpetology, Florida Museum of Natural History, Dickinson Hall, University of Florida, Gainesville, Florida 32611, USA (e-mail: kenneyk@flmnh.ufl.edu).

***DIPSOSAURUS DORSALIS* (Desert Iguana). REPRODUCTION BAJA CALIFORNIA SUR.** *Dipsosaurus dorsalis* ranges from southern Nevada to the tip of Baja California (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 533 pp.). Detailed information on *D. dorsalis* reproduction in southern California was reported by Mayhew (1971. Herpetologica 27:57–77). Previous information on reproduction of *D. dorsalis* in Baja California Sur was reported by Asplund (1967. Amer. Midl. Nat. 77:462–475) and Grismer (2002. Amphibians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. Calif. Press, Berkeley. 399 pp.). The purpose of this note is

TABLE 1. Monthly stages in the testicular cycle of 27 *Dipsosaurus dorsalis* from Baja California Sur, Mexico.

Month	N	Regressed	Recrudescence	Spermiogenesis	Late Spermiogenesis
May	9	0	0	9	0
June	1	1	0	0	0
July	9	2	4	1	2

July	5	4	0	1
August	6	6	0	0

to report additional information on reproduction of *D. dorsalis* from Baja California Sur.

A sample of 51 *D. dorsalis* collected from 1949 to 1978 at the southern tip of Baja California Sur, Mexico (between 24.1666°N, 110.3000°W and 22.8800°N, 109.9000°W), consisting of 27 adult males (mean SVL = 119.1 mm ± 8.3 SD, range = 105–134 mm), 14 adult females (mean SVL = 107.0 mm ± 10.8 SD, range = 93–127 mm), 8 subadult males (mean SVL = 93.1 mm ± 6.3 SD, range = 80–98 mm), 2 subadult females (mean SVL = 89.0 mm ± 0.71 SD, range = 88–89 mm) was examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA; LACM 17133–17136, 17138, 17154–17156, 17159, 17161, 17163–17167, 17173–17175, 17180–17191, 17193–17196, 17199–17201, 17204, 17205, 17207, 127939, 127940, 127943, 127946–127950, 127952, 127955, 127956.

A small incision was made in the lower part of the abdomen and the left gonad was removed for histological examination. Gonads were embedded in paraffin, sections were cut at 5µm, and stained with Harris hematoxylin followed by eosin counterstain. Oviductal eggs were counted. Histology slides were deposited in LACM.

Four stages were noted in the testicular cycle (Table1): 1) regressed, seminiferous tubules contain mainly spermatogonia and Sertoli cells; 2) recrudescence, proliferation of germ cells for the next period of spermiogenesis is in progress, primary spermatocytes predominate; 3) spermiogenesis, lumina of seminiferous tubules lined by clusters of sperm or metamorphosing spermatids; 4) late spermiogenesis, only a few rows of germinal cells remain, fewer sperm present in comparison to stage 3. Spermiogenesis occurred in May and concluded in July. Recrudescence was underway in July and August. The smallest reproductively active male (LACM 127940) (undergoing spermiogenesis), measured 106 mm SVL and was collected in May 1978. This is smaller than the minimum size (115 mm SVL) reported by Mayhew (1971, *op. cit.*) for reproductively active *D. dorsalis* males in California.

Three stages were noted in the ovarian cycle (Table 2): 1) quiescent, no yolk deposition; 2) early yolk deposition, basophilic vitellogenic granules are present; 3) oviductal eggs are present. Early yolk deposition occurs in May. Ovarian activity concludes by August. One July female (LACM 17201) contained six oviductal eggs. The smallest reproductively female (LACM 127946) exhibited early yolk deposition, measured 93 mm SVL and was collected in May 1978. This is smaller than the minimum size (110 mm SVL) reported by Mayhew (1971, *op. cit.*) for reproductively active *D. dorsalis* females in California.

My findings support Asplund (1967, *op. cit.*) who reported reproduction in *D. dorsalis* had ceased in August in the Cape Region of Baja California Sur. It appears the reproductive cycles of *D. dorsalis* are in synchrony in both California (Mayhew 1971, *op. cit.*) and Baja California Sur.

I thank Greg Pauley (LACM) for permission to examine *D. dorsalis*.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, PO Box 634, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***GEKKO JAPONICUS* (Japanese Gecko). SAP FEEDING.** *Gekko japonicus* is a small gecko (up to 73 mm SVL) occurring in Japan (Ota and Tanaka 1996. The Encyclopaedia of Animals in Japan 5, Amphibians, Reptiles, Chondrichthyes. Heibonsha, Tokyo, Japan. 69 pp.). On the basis of anecdotal information, this species is believed to inhabit urban areas almost entirely (Ota and Tanaka 1996, *op. cit.*). *Gekko japonicus* gathers around artificial lights on buildings and other anthropogenic structures at night to forage on insects that are attracted by the lights, such as moths, leaf beetles, and mayflies (Ota and Tanaka 1996, *op. cit.*; Werner et al. 1997. Asiatic Herpetol. Res. 7:153–165). Ota and Tanaka (1996, *op. cit.*) suggested coastal rocky areas and forests as the original habitats of *G. japonicus*. No ecological studies have shown the foraging behavior of *G. japonicus* in its natural habitat. Here, we report sap-feeding behavior by *G. japonicus* in a dark forest.

Our field survey was conducted in the coppice areas at the Kitashirakawa Experimental Station of the Field Science Education and Research Center, Kyoto University (35.0325°N, 135.7855°E, datum WGS84; 67 m elev.) and Yoshidayama Mountain (35.0227°N, 135.7838°E to 35.0286°N, 135.7886°E; 74–110 m elev.), Kyoto, Japan. We observed geckos licking the sap of the Japanese Willowleaf Oak (*Quercus salicina*) in the Kitashirakawa Experimental Station on 10 days in July and August 2010. On Yoshidayama Mountain, similar behaviors were observed by the geckos on Sawtooth Oak (*Quercus acutissima*) on 9 July 2010, 15 and 29 June 2012. During these surveys, we observed 14 *G. japonicus* individuals licking sap from trees. They usually did not move on the tree trunk or branches for several minutes and licked a small patch of tree sap. During the 2-min detailed observation on 29 June 2012, the gecko consumed sap for 19 sec by licking it 14 times. On one occasion (9 July 2010), we observed a *G. japonicus* consume a moth that was attracted by the sap from the Sawtooth Oak on Yoshidayama Mountain. After 1 min of tree-sap feeding by the gecko, a moth (Catocalinae) flew to the sap site of the tree trunk near the gecko. The gecko stopped licking the sap and captured the moth. Because we observed many moths and beetles attracted by the tree sap at night, we assumed that geckos might use the patch of tree sap as a sit-and-wait location to forage for insects attracted to the tree sap. However, further observations are required to evaluate the relative importance of sap feeding of *G. japonicus* in forest habitats.

To our knowledge, this is the first study to show a *Gekko* species using tree sap as a resource for direct ingestion of the sap and foraging for insect prey. However, in several species of lizards, it is considered that tree sap could be a valuable food resource

because of the high concentration of sugars and nutrients (Greer 1989. The Biology and Evolution of Australian Lizards. Surrey Beatty and Sons, Chipping Norton, Sydney, Australia. 264 pp.). Therefore, tree sap consumption by *Gekko* species may be more widespread than was previously considered, especially in several congeners that inhabit forest areas (e.g., Aowphol et al. 2006. Amphibia-Reptilia 27:491–503).

***HELODERMA HORRIDUM CHARLESBOGERTI* (Guatemalan Beaded Lizard). WILD REPRODUCTIVE ECOLOGY.** *Heloderma horridum charlesbogerti* is an endangered venomous lizard endemic to the seasonally dry tropical forests of Motagua Valley in eastern Guatemala (Campbell and Vannini 1988. J. Herpetol. 22:457–468).

We conducted a four-year radio-tracking study from July 2004 to September 2008 to determine the ecology and behavior of this species. Lizards were fitted with a radio transmitter (CHP-5P by Telonics, Mesa, Arizona, USA) and tracked using an ATS FieldMaster FM100 Receptor. The transmitters were attached within the second and third tail ring of each lizard (approximately 20 mm posterior to the vent), and to improve the security of the transmitters, they were fixed using duct tape (Truper, USA), with care taken not to obstruct the cloaca. Each individual was also marked with PIT-tags (AVID microchips, Los Angeles, California, USA) inserted at the level of the right forelimb.

One of the radiotracked females (No. 094.519.273) was gravid at the beginning of November 2006. This was verified by detecting egg masses in her belly by direct ventral palpation. During the second week of November 2006 this female entered a burrow probably made by an armadillo (*Dasypus novemcinctus*), in which she remained for 12 days at a depth of 2.5 m. After this time, the female emerged notably thinner (late November 2006) and a tactile exam revealed that eggs has been laid inside this burrow. Five months later (early April 2007) marks on the entrance of the burrow indicated that juveniles had left this underground retreat. Internal inspection of the burrow revealed four hatched egg shell remains.

The nest described above was monitored with data loggers. Simultaneous data of relative humidity (%), temperature (°C), and dew point (°C) were recorded at a depth of 1 m in the underground shelter of female No. 094.519.273 nest. This was made using EL-USB-2 preprogrammed Lascar® data loggers. The data storage time was settled to record every 5 min. Means are given ± 1 SD.

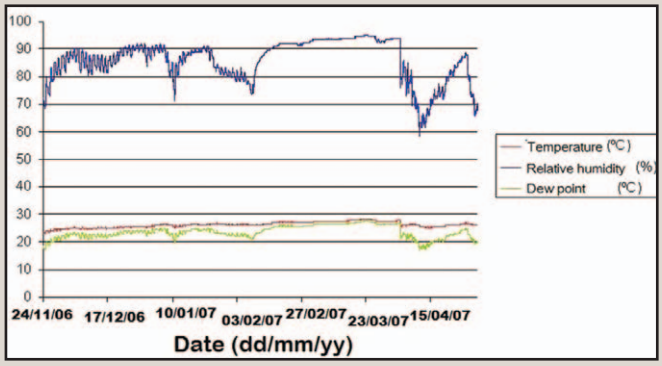

FIG. 1. Microclimatic parameters of the incubation period of a nest of *Heloderma horridum charlesbogerti* in the wild monitored from 24 November 2006 to 21 April 2007.

The incubation period of this nest was 149 days. The average incubation temperature was 26.36 ± 1.09°C, average relative humidity was 82.16 ± 9.76%, and average dew point temperature was 22.97 ± 2.38°C. These data were taken from 24 November 2006 to 21 April 2007.

The temperature range inside the nest was between 23–29°C. The relative humidity ranged from 58.5% to 95%, with the lowest percentages occurring near the end of the incubation period. The dew point temperature varied from 16.8 to 27.6°C. There were no differences between the nest temperature and the dew point temperature inside the shelter during the first four months of incubation. This implies that for successful incubation the eggs of this species require a humidified or nearly saturated environment, but with no direct contact with water.

The incubation time of a monitored nest (149 days) agrees with previous reports on captive incubations of eggs of *H. h. charlesbogerti* at San Diego Zoo, which varied between 145 to 164 days (Owens 2006. Iguana 13:212–215). These incubation periods are much less than those reported in captivity for other subspecies of *H. horridum* which vary from 201 to 215 days (Beck 2005. Biology of Gila Monsters and Beaded Lizards. Univ. California Press, Los Angeles. 211 pp.). The microclimate data of the nest monitored and presented in this note are the first observation and microclimate data gathering of a wild nest of any *Heloderma* species in nature (Beck 1990. J. Herpetol. 24:54–68; Beck 2005, *op. cit.*; Beck and Jennings 2003. Herpetol. Monogr. 17:111–129; Beck and Lowe 1991. J. Herpetol. 25:395–406; Campbell and Vannini, *op. cit.*; Jones 1983. Herpetologica 39:247–253). The data reported here will be of great relevance for further captive breeding programs on this endangered species, as captive incubation in *H. h. charlesbogerti* has been reported to be problematic (Owens, *op. cit.*).

Fieldwork was conducted under CONAP scientific research permits. Funding was provided by grants from Zoo Atlanta, IRCF, Eli Lilly Co., Disney Worldwide Conservation Fund, San Diego Zoo, Oklahoma City Zoo, Idea Wild, and The Nature Conservancy. This work was part of a Master's thesis of D. Ariano-Sánchez at Universidad de Costa Rica. Field assistance was provided by Erick Lopez, Cristian Beza, and Pablo Salazar.

***LEPOSOMA PARIETALE*. ENDOPARASITES.** *Leposoma parietale* is known from the Amazonian slopes of the Andes in southeastern Colombia, eastern Ecuador and northeastern Peru where it inhabits leaflitter (Avila-Pires. 1995. Lizards of Brazilian Amazonia [Reptilia: Squamata]. Zoologische Verhandelingen 299:1–706). We know of no reports of helminths for *L. parietale*. The purpose of this note is to establish the initial helminth list for this gymnophthalmid lizard.

Eleven *L. parietale* (mean SVL = 32.3 mm ± 3.1 SD, range = 27–35 mm) from the herpetology collection of the Sam Noble Museum (OMNH, The University of Oklahoma, Norman, USA) were examined for helminths, all from Ecuador, including specimens from Napo Province, Jatun Sacha (OMNH 36379; 0.98333°S, 77.81667°W, WGS 84; elev. 400 m) collected in April 1989, and

from Sucumbios Province, Reserva Faunistica Cuyabeno, Estación Biología da Universidad Católica (Quito) (OMNH 36456–36467; 0°S, 76.11667°W, WGS 84; elev. 260 m), collected in February, March, and April 1994. The stomachs had been previously removed and were not available for examination. The small and large intestines were removed, opened, and examined under a dissecting microscope. Cestodes were regressively stained in hematoxylin, mounted in balsam on a microscope slide, cover slipped, and studied under a compound microscope as a whole-emount. Nematodes were removed, placed separately on microscope slides, cleared in a drop of lactophenol, cover slipped, and studied under a compound microscope. One species of Cestoda, *Tejidotaenia appendiculata* (N = 3) was found in the small intestine of OMNH 36379. Two species of Nematoda were found, including *Cosmocerca vrcibradici* in the large intestine of OMNH 36464 (N = 2) and OMNH 36467 (N = 1) and *Oswaldocruzia vitti* (1 each) in the large intestine of OMNH 36459 and 36460. Prevalence, number infected/number examined × 100 = 9.0% for *T. appendiculata,* 18.1% for both *C. vrcibradici* and *O.* vitti. Mean infection intensity (mean number infected individuals) was 1.50 ± 0.71, range: 1–2 for *C. vrcibradici.* Helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA as *Tejidotaenia appendiculata* (USNPC 106354), *Cosmocerca vrcibradici* (USNPC 106355), and *Oswaldocruzia vitti* (USNPC 106356).

Tejidotaenia appendiculata (originally *Proteocephalus appendiculatus* from *Tupinambis nigropunctatus* [currently *T. teguixin*] collected in Surinam) was redescribed from the same host collected in Brazil (Rego and de Chambrier 2000. Mem. Inst. Oswaldo Cruz 95:161–165). *Leposoma parietale* represents the second reported host for *T. appendicualta*; Ecuador is a new locality record. *Cosmocerca vrcibradici* was described from the gymnopthalmid *Prionodactylus eigenmanni* (currently *Cercosaura eigenmanni*) from Rondônia State, Brazil (Bursey and Goldberg 2004. J. Parasitol. 90:140–145). Other hosts are in Goldberg et al. (2010. Herpetol. Rev. 41:495–496). *Oswaldocruzia vitti* was described from *P. eigenmanni* from Amazonas State, Brazil by Bursey and Goldberg (*op. cit.*); a host list is in Goldberg et al. (2013. Herpetol. Rev. 44, *in press*). *Tejidotaenia appendiculata, Cosmocerca vrcibradici* and *Oswaldocruzia vitti* comprise the initial parasite list for *L. parietale.*

We thank Jessa L. Watters (OMNH) for facilitating the loan.

***LEPOSOMA PERCARINATUM* (Muller's Tegu). ENDOPARASITES.** *Leposoma percarinatum* is known from northern South America east of the Andes where it inhabits leaflitter, frequently close to water (Avila-Pires. 1995. Lizards of Brazilian Amazonia (Reptilia: Squamata). Zoologische Verhandelingen 299:1–706). We know of no reports of helminths for *L. percarinatum.* The purpose of this note is to establish the initial helminth list for *L. percarinatum.*

Twelve *L. percarinatum* females (mean SVL = 29.2 mm ± 5.1 SD, range = 23–37 mm) were examined for helminths from the herpetology collection of the Sam Noble Museum (OMNH, The University of Oklahoma, Norman, USA) collected July 1993 (OMNH 36344–36355) in Roraima State, Brazil, 7.0 km E Rio Ajarani (1.55000°S, 61.26666°W, WGS 84; elev. 66 m). The stomachs had been previously removed and were not available for examination. The small and large intestine were removed, opened and examined under a dissecting microscope. The only nematode found was from the small intestine of OMNH 36355. It was placed on a microscope slide, cleared in a drop of lactophenol, cover slipped and studied under a compound microscope. It was identified as an adult female *Oswaldocruzia vitti.* Prevalence (number infected/number examined × 100 = 8.3%). The helminth was deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA as *Oswaldocruzia vitti* (USNPC 106357).

Oswaldocruzia vitti was described from *Prionodactylus eigenmanni* (currently *Cercosaura eigenmanni*) from Amazonas Province, Brazil by Bursey and Goldberg (2004. J. Parasitol. 90:140–145). A host list is in Goldberg et al. (2013. Herpetol. Rev. 44 *in press*). *Leposoma percarinatum* represents a new host record for *O. vitti.*

We thank Jessa L. Watters (OMNH) for facilitating the loan.

***LEPOSTERNON* SP. PREDATION.** During the analysis of stomach contents of a young female Crab-eating Fox (*Cerdocyon thous*) in the Laboratório de Ecologia of the Universidade Veiga de Almeida, Rio de Janeiro, Brazil, we collected body parts of an unidentified species of *Leposternon* sp. The specimen of *C. thous* was a road kill, collected on 2 December 2009, on the BR-040 highway, at km number 97 (22.583°S, 43.260°W; datum SAD 69), in the locality of Xerém, Duque de Caxias, Rio de Janeiro state, Brazil. The Crab-eating Fox is a medium-sized canid that is widely distributed in Brazil (Reis et al. 2011. Mamíferos do Brasil. 2ª edição. Londrina. 442 pp.), which has an omnivorous diet, including plants (fruits), small mammals, arthropods, fishes, anurans, birds, carrion, and reptiles (turtle eggs, lizards, and snakes) having been reported in the literature (Bueno and Motta-Júnior 2004. Rev. Chil. Hist. Nat. 77:5–14; Gatti et al. 2006. Jour. Trop. Ecol. 22:227–230; Gomes et al. 2012. Herpetol. Notes 5:463–466; Juarez and Marinho-Filho 2002. J. Mammal. 83:925–933; Reis et al. 2011, *op. cit*; Rocha et al. 2004. Rev. Bras. Zool. 21:871–876; Uchoa et al. 2004. Cad. Biodiv. 4:67–74; Pedó et al. 2006. Rev. Bras. Zool. 23:637–641; Vieira and Port 2007. J. Zool. 272:57–63). Prior to the report presented here, reptiles reported in the diet of this wild canid are the lizards *Brasiliscincus agilis, Ameivula littoralis, Ameiva ameiva, Vanzosaura rubricauda, Tropidurus* sp., *Anolis* sp., *Mabuya* sp., and *Ameiva* sp.; and the snakes *Typhlops brongersmianus* and *Bothropoides jararaca* (Gatti et al., *op. cit.*; Gomes et al. 2012, *op. cit.* Juarez and Marinho-Filho, *op. cit.*; Raíces and Bergallo, 2010. Neotrop. Biol. Conserv. 5:24–30; Rocha et al., *op. cit.*; Rocha et al. 2008. Rev. Bras. Zool. 25:594–600).

The head of *Leposternon* species are characterized by the presence of the rostral and nasals fused into a single shield, and by having nostrils with the openings on the ventral surface of the

snout (Perez and Ribeiro 2008. Check List 4:291–294; Peters and Orejas-Miranda 1970. Catalogue of Neotropical Squamata Part I. Snakes. U.S. Nat. Mus. Bull. 347 pp.), which was observed in the head of the specimen of the current study. *Leposternon* species are differentiated from each other by the size and position of the azygous, by the size of the pectoral shields, and the number of rows of postpectoral shields (Barros Filho and Valverde 1996. Sitientibus 14:57–68; Perez and Ribeiro, *op. cit.*; Peters and Orejas-Miranda, *op. cit.*). According to Perez and Ribeiro (*op. cit.*) and Rocha et al. (2004. Publ. Avul. Mus. Nac. 104:3–23), *Leposternon* is represented by four species in the Rio de Janeiro state: *L. infraorbitale*, *L. microcephalum*, *L. scutigerum*, and *L. wuchereri*. In the current study, it was not possible to identify the *Leposternon* species because of missing body parts. Therefore, the present study is the first report of a *Leposternon* sp. as a food item in the diet of Crab-eating Fox from Brazil.

***PHRYNOSOMA CORNUTUM* (Texas Horned Lizard). PREDATION.** Despite the Texas Horned Lizard's large protective horns and spiny scales, some species of snakes are able to successfully consume them. Common snake predators of *Phrynosoma cornutum* include Coachwhips and Sonoran Whipsnakes (*Masticophis flagellum* and *M. bilineatus*) and Western Diamondback Rattlesnakes (*Crotalus atrox*) (Sherbrooke 2003. Introduction to Horned Lizards of North America. Univ. California Press. Berkeley, California. 177 pp.; Sherbrooke et al. 2012. Herpetol. Rev. 40:386–391). Here I report on another successful serpent predator on *P. cornutum*, the Broad-banded Copperhead (*Agkistrodon contortrix laticinctus*).

A female *P. cornutum* was recently discovered in the stomach of an *A. c. laticinctus* during a radio telemetry study. The captive-hatched, three-year-old *P. cornutum* was released on a private site in Parker Co., Texas, USA, on 08 September 2011 as part of a reintroduction project and had been tracked using radio telemetry for eight months. She was outfitted with a radio transmitter glued to her back and was last sighted near the edge of an oak motte on 2 May 2012. Six days later on 8 May 2012, a weak radio signal led to an *A. c. laticinctus* coiled under a tangle of bramble within the oak motte. The snake was captured and radiographed (Fig. 1). The radiograph confirmed suspicions that the horned lizard had been consumed. The transmitter was later passed safely through the snake's digestive system on 30 May 2012. The *P. cornutum* weighed approximately 46 g prior to being consumed and the *A. c. laticinctus* measured 69.2 cm total length and weighed 136.1 g after the horned lizard was digested and the transmitter was expelled.

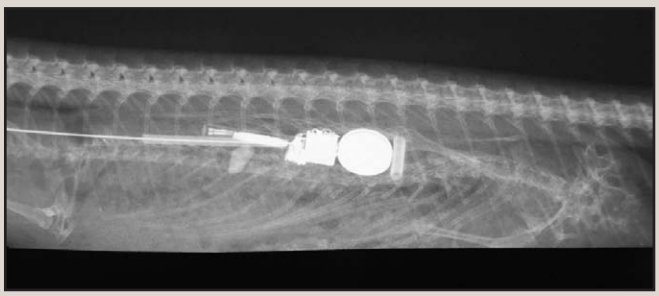

PHOTO COURTESY OF FORT WORTH ZOO

FIG. 1. Radiograph of an *Agkistrodon contortrix laticinctus* showing ingested *Phrynosoma cornutum* with radio transmitter.

These observations were made while conducting research with permission of the Texas Parks and Wildlife Department and the private landowners. Assistance with the radiograph was provided by the Fort Worth Zoo veterinary staff and financial support for the radio telemetry work was granted through the Fort Worth and Phoenix Zoos. I thank all, including the FWZ herpetology staff, for their continued support of this project.

***PHRYNOSOMA CORNUTUM* (Texas Horned Lizard). NOCTURNAL ACTIVITY.** On 20 May 2009, two of us (RALR and HG) observed copulation in *Phrynosoma cornutum* (SVL 93 mm, male; 73 mm, female) at 2130 h during a full moon in desert thornscrub habitat in the Bolsón of Mapimí, Chihuahua, Mexico (26.843360°N, 103.860004°W, 1115 m elev.). This behavior was observed at a distance of 4 m from the lizards. After the copulation ended, we collected data on body temperature for both individuals using a digital thermometer (29.1°C, male; 31.2°C, female). We also recorded substrate temperature (29.1°C) at the exact point of observation and air temperature (23.6°C) at 1 cm above the substrate where the lizards were found. That day, sunset had occurred at 1937 h and the temperatures recorded at the nearest weather station (25.53°N, 103.45°W; 1124 m elev.) were on average 24.4°C, maximum 33.5°C, and minimum 19°C.

According to Huey (1982. *In* Gans and Pough [eds.], Biology of the Reptilia, Vol. 12, Physiology C, pp. 25–91. Academic Press, New York) some diurnal reptiles voluntarily select relatively low T_b after sunset (e.g., *Gopherus agassizii*, *Gambelia wislizenii;* see also Martínez-Méndez et al. 2013. Herpetol. Rev. 44:148 for *Sceloporus clarkii*), which may prolong potential foraging time by reducing the animals' dependence on solar radiation for activity. Furthermore, previous studies (Dunham 1993. *In* Kareiva et al. [eds.], Biotic Interactions and Global Change, pp. 95–119. Sinauer Associates, Sunderland, Massachusetts; Huey et al. 2010. Science 328:832–833; Sinervo et al. 2010. Science. 328:894–899) have suggested that if diurnal lizards are exposed to environmental temperatures greater than their thermal preferences, thus shortening activity time and forcing retreat, then the net energy gain becomes insufficient. In the case reported here, horned lizards were observed to be reproductively active almost two hours after sunset while remaining within their preferred body temperature range and above minimum voluntary temperatures (Prieto and Whitford 1971. Copeia 1971:498–504). This observation suggests the possibility that *P. cornutum* had fewer opportunities to complete their daily activities during daylight, due to high diurnal temperatures. Therefore, copulations after sunset may increase their chances of reproducing, which may be an adaptive response for individuals that fail to perform their activities during the day (i.e., feeding, breeding, nesting, etc.).

In addition, we suggest that the full moonlight helps to prolong activity time at night, as long as the degree of voluntary hypothermia does not fall below the level of the minimum voluntary temperature. Finally, more data are necessary to determine whether this behavior is common in *Phrynosoma*, and other diurnal desert lizards as well, to evaluate the thermal efficiency of *P. cornutum* and the thermal quality of its habitat.

We thank UNAM PAPIIT/DGAPA (IN224208 and IN215011) for providing financial support for field work and Elizabeth Bastiaans for helpful comments that improved the manuscript.

RAFAEL A. LARA-RESENDIZ, Posgrado en Ciencias Biológicas, Instituto de Biología, Laboratorio de Herpetología, Universidad Nacional Autónoma de México, A.P. 70515, C.P. 04510, Distrito Federal, México (e-mail: rlara@ibiologia.unam.mx); **HECTOR GADSDEN**, Instituto de Ecología, A.C., Miguel de Cervantes No. 120, Complejo Industrial Chihuahua, C.P. 31109, Chihuahua, Chihuahua, México (e-mail: hector.gadsden@inecol.edu.mx); **FAUSTO R. MENDEZ-DE LA CRUZ**, Laboratorio de Herpetología, Departamento de Zoología, Instituto de Biología, Universidad Nacional Autónoma de México, A.P. 70515, C.P. 04510, Distrito Federal, México (e-mail: faustor@ibiologia.unam.mx).

***PHRYNOSOMA HERNANDESI* (Greater Short-horned Lizard). PREDATION.** Greater Short-horned Lizards are known to be preyed upon by a variety of predators, including black widow spiders (*Latrodectus mactans*) (Painter and Kamees 2010. Herpetol. Rev. 41:227), Striped Whipsnakes (*Coluber taeniatus*), Burrowing Owls (*Athene cunicularia*) (Hammerson 1999. Amphibians and Reptiles in Colorado. Univ. Press Colorado and Colorado Division of Wildlife, Denver. 484 pp.), and Ferruginous Hawks (*Buteo regalis*) (Cartron et al. 2004. Southwest. Nat. 49:270–276). Here we report the first documentation to our knowledge of Chihuahuan Ravens (*Corvus cryptoleucus*) preying on *P. hernandesi*.

Previous work establishes that Chihuahuan Ravens are omnivorous birds that are known to include lizards, including *Phrynosoma* sp. in their diet (Aldous 1942. The White-necked Raven in Relation to Agriculture. Res. Rep. 5. U.S. Fish Wildl. Serv.; Bednarz and Raitt 2002. *In* A. Poole [ed.], The Birds of North America Online. Cornell Lab of Ornithology, Ithaca, New York). However, most of the available dietary information on this bird species was provided by Aldous (1942, *op. cit.*), who examined the stomach contents of 827 ravens, the majority of them originating from agricultural regions in Texas. Though species-level information is not included for the horned lizards that were documented in raven diets for that study, the likely species would be *Phrynosoma cornutum* based on the origins of the birds dissected.

On 21 July 2007, we observed the predated carcasses of 23 adult *P. hernandesi* under a Chihuahuan Raven nest situated on a power-line pole in desert grassland ca. 700 m W of NM State Rd. 47 and 4.1 km N of US Route 60, Socorro Co., New Mexico, USA (34.468736°N, 106.570816°W, WGS84; 1616 m elev.). We examined several freshly killed (carcasses still supple with no degradation) horned lizards (deposited into the Museum of Southwestern Biology, Univ. of New Mexico as MSB 75695 and 75699) and noted that ravens had extracted the viscera through a single large cut on the ventral side, discarding the rest of the carcass (Fig. 1). Chihuahuan Ravens may have the potential to be locally important predators on Greater Short-horned Lizards.

***PHYLLODACTYLUS TUBERCULOSUS* (Yellow-Bellied Gecko). BODY TEMPERATURE.** Monitoring thermal requirements and thermoregulatory behavior of reptiles is crucial for understanding effects of global warming on species (Sinervo et al. 2010. Science 328:894–899; Paranjpe et al. 2012. Proc. Meas. Behav. 460–462). Data on body temperature for Mexican nocturnal lizards is actually quite rare in the literature (Huey 1982, *In* C. Gans and F. H. Pough [eds.], Biology of the Reptilia, Volume 12, Physiology C, pp. 25–91. Academic Press, New York; Supporting Online Material for Sinervo et al. 2010, *op. cit.*). *Phyllodactylus tuberculosus* is a nocturnal lizard that inhabits arid to semiarid regions of the Neotropics and occurs from southern Sonora, Mexico to southern Costa Rica, at elevations of 0 to 1230 m (Dixon 1964. New Mexico State Univ. Sci. Bull. 64:1–139; Blair et al. 2012. Cons. Genet. Resour. 4:807–810). The thermal biology of this species has received little attention. Hence, here we present data on *P. tuberculosus* thermal ecology.

During October 2012, we conducted field work in tropical dry forest habitat located in Alamos, Sonora, Mexico (27.0596°N, 108.9465°W; elev. 439 m). The data presented are based on 21 adults (> 40 mm; Dixon 1964, *op. cit.*) of *P. tuberculosus* captured by noose and hand, with SVL measured to 0.05 mm. Body temperature (T_b) was recorded using a digital thermometer. We also recorded substrate temperature (T_s) at the exact point of observation and air temperature (T_a) 1 cm above the substrate where the gecko was found. Sex was not determined in the field because obvious sexual dimorphism was lacking.

Mean SVL was 59.8 mm (SD = 12.07, range = 40–78 mm). Mean field T_b was 27.2°C (SD = 2.35°C, range = 24.2–31.1°C). Mean substrate temperature was 24.1°C (SD = 1.79°C, range = 22–29.2°C) and mean T_a was 23.3°C (SD = 2.28°C, range = 21.3–32°C). Body size was unrelated to T_b (Spearman Rank Correlation: r = -0.36, P = 0.10, N = 21). A positive and significant correlation was found between T_b and the temperature of the microhabitat (Spearman Rank Correlation: r = 0.74, P < 0.0001, N = 21, based on substrate; r = 0.71, P = 0.0002, N = 21, based on air). Geckos were found active from 1830 to 2200 h.

These results show that *P. tuberculosus* analyzed in this study were thermopassive, a mechanism where individuals do not need to invest time and energy actively selecting microhabitats for thermoregulation during night activity (Huey and Slatkin 1976. Q. Rev. Biol. 51:363–384). Brattstrom (1965. Am. Midl. Nat. 73:376–422) reported a mean T_b of 22.7°C (range = 16.5–30°C) for this species, but measurements were taken only during the morning (1000–1100 h). Previous thermal ecology studies of nocturnal geckos have demonstrated that T_b can vary between day (photophase) and night (scotophase) (e.g., Angilletta et al. 1999. Herpetologica 55:212–222; Dial 1978. Herpetologica 32:194–201;

Sievert and Hutchison 1988. Herpetologica 44:266–273). Therefore, we propose that future studies evaluate the thermal efficiency of this gecko and the microhabitat thermal profile available in both phases.

We thank Christopher Blair for helpful comments that improved the manuscript.

RAFAEL A. LARA-RESENDIZ (e-mail: rlara@ibiologia.unam.mx), **DIEGO M. ARENAS-MORENO** (e-mail: daigo@ibiologia.unam.mx), Posgrado en Ciencias Biológicas, Instituto de Biología, Universidad Nacional Autónoma de México, AP 70515, CP 04510, Distrito Federal, México; **FERNANDO I. VALLE-JIMENEZ,** Universidad de Sonora, CP 83000 Hermosillo, Sonora, México (e-mail: bioisai@gmail.com).

***POGONA BARBATA* (Eastern Bearded Dragon). DIET.** *Pogona barbata* is a large agamid widespread on the coast and ranges of eastern Australia, with reported diet ranging from vegetation such as soft fleshy leaves, flowers, and fruit, terrestrial and flying arthropods, to small vertebrates. However there are few records of predation by any wild Australian lizard where arthropod prey items are identified to species level; for example, several authors of general references on Australian herpetology mention cicadas as one of the insect groups included in lizard diets but do not provide species identification or details of predator-prey interactions. This note reports observations of an instance of predation by *P. barbata* on the endemic Australian cicada *Henicopsaltria eydouxii* (Hemiptera: Homoptera: Cicadidae), a medium- to large-sized insect species (~50 mm total length).

On 17 February 2007, ~0915 h, at Mount Kuring-gai (a northern suburb of metropolitan Sydney), New South Wales, Australia (33.636639°S, 151.129778°E, WGS84; 213 m elev.), during the course of the field component of statutory ecological requirements of environmental assessment in connection with a proposed residential development, TJH observed a small (probable subadult) *P. barbata* (27 cm total length) resting in diffuse sunlight in a canopy-foliage-shaded area on yellow sand adjacent to a small *Dillwynia retorta* (Fabaceae) shrub ~0.8 m height on a sunny day (1/8 cloud cover). The *P. barbata* held in its jaws a freshly dead *H. eydouxii*; the lizard was motionless upon initial detection, despite the high temperature (30–32°C) and humidity (70–80%). The cicada also did not display movement. Approached closer, the lizard remained motionless even when touched lightly by the observer along the back; it did not move the body or attempt escape or threat display, although movement and orientation of the eyes indicated that the lizard was aware of the observer's presence; neither animal was collected. Habitat in the area comprised a Hawkesbury Sandstone ridge with semi-cleared remnant Dry Sclerophyll Woodland dominated by *Eucalyptus punctata, E. eximia, E. sclerophylla* (Myrtaceae), *Banksia ericifolia, B. serrata* (Proteaceae), and *Allocasuarina littoralis* (Casuarinaceae), and a heath understory of species of many plant taxa, principally Fabaceae, Epacridaceae, and Proteaceae. Initiation of the interaction was not observed, however it is possible that the lizard had either captured the cicada on the trunk of a tree or on the ground, or scavenged a recently deceased individual (cicada adults are very short-lived); whichever the case, *H. eydouxii* is undoubtedly a dietary inclusion of *P. barbata*, a large single item that in the above case would have provided substantial nutrient resources for the lizard.

H. eydouxii is a widespread cicada in coastal areas from southeastern Queensland to southern New South Wales; adults are usually found resting on the trunks and main branches of large *Eucalyptus* spp. (Myrtaceae) but are also known to oviposit on the branches of dead *Casuarina* (*sensu lato*; probably includes *Allocasuarina* spp.) trees (Moulds 1990. Australian Cicadas. New South Wales University Press, Kensington. 216 pp.); although this author noted generally that lizards prey on cicadas, specific examples of lizard predation on any cicada and the identity of predators and prey were not provided. There appear to be no other relevant references, and the present record is therefore of interest, particularly the relatively large size of this single prey item.

DEAN C. METCALFE, PO Box 4056, Werrington, New South Wales, Australia 2747 (e-mail: dean_metcalfe@yahoo.com.au); **TREVOR J. HAWKESWOOD**, PO Box 842, Richmond, New South Wales, Australia 2753 (e-mail: hawkeswoodtj@hotmail.com).

***SCELOPORUS GRAMMICUS* (Mesquite Lizard). SELECTED BODY TEMPERATURE.** Data on preferred body temperature is actually quite rare (Sinervo et al. 2010. Science 328:894–899) because measurement in a laboratory thermal gradient under standard conditions is required (Huey 1982. *In* Gans and Pough [eds.], Biology of the Reptilia, Vol. 12, Physiology C, pp. 25–91. Academic Press, New York). *Sceloporus grammicus* is a geographically widespread viviparous lizard that exhibits considerable variation in habitats occupied (Köhler and Heimes 2002. Stachelleguane. Herpeton. 174 pp.). There have been several reports detailing thermal ecology in *S. grammicus* in different environments (Andrews et al. 1997. Copeia 1997:108–115; Lemos-Espinal and Ballinger 1995. Can. J. Zool. 73:2184–2191; Woolrich-Piña et al. 2006. Acta Zool. Mex. 22:137–150), but the selected body temperature has not been documented. Here, we describe thermal preferences in *S. grammicus* under laboratory conditions.

During May 2012, we conducted field work in La Malinche Volcano, Tlaxcala (19.2379°N, 97.9770°W; 3030 m elev.) located in a forested area dominated by pine. The data presented are based on 15 adults (> 49 mm SVL; 9 females and 6 males) of *S. grammicus* captured by noose.

In the laboratory, the lizards were separated by gender and maintained at 25°C in plastic containers with soil, branches, and grass, and hydrated with a sprinkler. Laboratory experiments were conducted two days after capture using a thermal gradient, which consisted of a polycarbonate box (150 cm long x 150 cm wide x 70 cm high) divided into ten tracks of 15 cm each to prevent interaction between lizards. The box was located in a room with a controlled temperature of 20°C and three 150 W lamps were placed at different heights over the box to offer the thermal gradient (20–50°C). Body temperature data was collected manually using a digital thermometer in the thermal gradient each hour between 1330 and 1930 h. We applied a nonparametric Kruskal-Wallis one-way test to analyze differences between all measurements of body temperature in the laboratory and we used a Mann-Whitney Rank test to analyze the differences between gender.

There were no statistically significant difference between measurements of temperature ($H_6 = 9.173$, $p = 0.164$) or between gender ($U = 1112.5$, $p = 0.169$). Mean preferred body temperature was 32.9°C (SD = 2.64°C, range = 25.3–37.6°C). Interquartile of 25% and 75% was 30.8°C and 35.0°C, respectively. These results suggest S. *grammicus* can be considered a eurythermic species due to the wide range of preferred temperatures in this species. Therefore, we propose to evaluate the thermal efficiency by monitoring mean thermal requirements and microhabitat temperatures across its distribution for understanding effects of global warming on this geographically widespread lizard.

We thank Estación Científica La Malinche, Fausto Méndez de la Cruz, and Margarita Martínez Gómez for the economic resources and the facilities.

RAFAEL A. LARA-RESENDIZ (e-mail: rlara@ibiologia.unam.mx) and **ANÍBAL H. DÍAZ DE LA VEGA-PÉREZ** (e-mail: ahelios@ibiologia.unam.mx), Posgrado en Ciencias Biológicas, Instituto de Biología, Laboratorio de Herpetología, Universidad Nacional Autónoma de México, AP 70515, CP 04510, Distrito Federal, México.

***SCELOPORUS OCCIDENTALIS LONGIPES* (Great Basin Fence Lizard). DIET.** On 2 July 2012, an adult *Sceloporus occidentalis longipes* was observed and photographed ingesting a hatchling conspecific on a cement walkway outside of a residence in Poway, California. Although cannibalism has been documented in *S. occidentalis* through the analysis of stomach contents (Johnson 1965. Herpetologica 21:114–117), to my knowledge there do not appear to be any photographs documenting cannibalism within this species in the wild.

FIG. 1. Adult *Sceloporus occidentalis longipes* cannibalizing a hatchling conspecific.

TAYLOR S. HENRY, 13945 Chancellor Way, Poway, California 92064, USA (e-mail: taylorshenry@yahoo.com)

***TUPINAMBIS MERIANAE* (Argentine Giant Tegu); *PANTHEROPHIS GUTTATUS* (Red Cornsnake). NON-PREDATORY KILLING.** *Tupinambis merianae* is an established invasive lizard in Florida, USA, where a population was discovered initially in Balm Boyette Scrub Preserve, Hillsborough Co. (Enge et al. 2006. *In* Proceedings 28th Annual Gopher Tortoise Council Meeting. Valdosta, Georgia; Engeman et al. 2011. Curr. Zool. 57:599–612). The threats posed by this species to native species are undetermined, although it has been observed using Gopher Tortoise (*Gopherus polyphemus*) burrows, where it potentially could have similar burrow usurpation and juvenile predation impacts as does another large invasive lizard in southern Florida, Gray's Spiny-tailed Iguana (*Ctenosaura similis*) (Avery et al. 2009. Herpetol. Rev. 40:435; Engeman et al. 2009. Herpetol. Rev. 40:84). We have been testing a variety of methods to detect and index populations of *T. merianae* and to investigate their tortoise burrow usage in Balm Boyette Scrub Preserve (Kaiser et al. 2011. *In* Proceedings 33rd Annual Gopher Tortoise Council Meeting. Orlando, Florida). We report here evidence from these investigations that *T. merianae* may pose a threat to snakes.

We used wildlife cameras to obtain still photographs and video recordings at 16 *G. polyphemus* burrow entrances (Kaiser et al., *op. cit.*). On 14 June 2011 at 0828 h EST, we obtained a video recording of a *T. merianae* (ca. 120 cm TL) attacking a Red Cornsnake (*Pantherophis guttatus*) (ca. 132 cm TL). The lizard was observed carrying and shaking the snake violently as it entered a tortoise burrow being monitored by one of our video cameras. Within 4 sec, the lizard emerged (the tail of the snake remained visible the entire time) still carrying and shaking the less active snake. Within another 4 sec, the lizard disappeared from view carrying the snake.

Adult *T. merianae* in Brazil occasionally feed on snakes (Mercolli and Yanosky 1994. Herpetol. J. 4:15–190), but this snake appeared too large for the lizard to consume. We cannot explain the lizard's behavior towards the snake, but a defense mechanism seems plausible, particularly since *C. similis* has been observed exhibiting this behavior in Florida (Engeman et al. 2009. Herpetol. Rev. 40:84–85). Janzen and Brodie (1995. J. Herpetol. 29:132–136) studied *C. similis* responses to color cues by using different color patterns on snake replicas and found that brightly colored replicas (red, yellow, black) elicited the most attacks. Engeman et al. (2009, *op. cit.*) observed a *C. similis* attack a Southern Black Racer (*Coluber constrictor priapus*) with a drab, monotone color and no pattern. The *P. guttatus* attacked by the *T. merianae* was a bright rust-red color, but we do not know whether its coloration was a contributing factor in the attack. The *T. merianae* was obviously willing to attack a snake, and more importantly, this agonistic behavior may have implications regarding its potential to impact snakes, including small individuals of the Eastern Indigo Snake (*Drymarchon couperi*), a federally threatened species. An introduced population of the Gold Tegu (*Tupinambis teguixin*) on the island of San Andrés, Colombia, was suspected of adversely impacting an endemic snake species (Fitzgerald et al. 2005. *In* Joint Annual Meeting of Ichthyologists and Herpetologists, Tampa, Florida). High-density populations of *T. merianae*, such as is apparently found in Balm Boyette Scrub Preserve, could negatively affect snake recruitment and numbers through such behavior.

***CROTALUS CATALINENSIS* (Santa Catalina Island Rattlesnake). DIET.** *Crotalus catalinensis* is a poorly understood rattlesnake endemic to Isla Santa Catalina, BCS, Mexico. Potential prey items of *C. catalinensis* include approximately 44 species of reptiles, birds, and mammals that occur or visit Isla Santa Catalina (Case et al. 2002. A New Island Biogeography of the Sea of Cortés. Oxford Univ. Press, New York. 669 pp.). However, only five species have been documented as prey items of *C. catalinensis* thus far: *Amphispiza bilineata* (Black-Throated Sparrow), *Sceloporus lineatulus* (Santa Catalina Island Spiny Lizard), *Peromyscus slevini* (Santa Catalina Island Deer Mouse), *Dipsosaurus catalinensis* (Santa Catalina Island Desert Iguana), and *Uta squamata* (Santa Catalina Side-Blotched Lizard; Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley. 409 pp.; Avila-Villegas et al. 2007. Copeia 2007:80–84; Avila-Villegas et al. 2004. Herpetol. Rev. 35:60). Grismer (*op. cit.*) speculated that juvenile *C. catalinensis* probably also consumes other small lizards, especially *Phyllodactylus bugastrolepis* (Santa Catalina Island Leaf-Toed Gecko).

While measuring specimens for another study, we recovered the regenerated tail of an *Aspidoscelis catalinensis* (Santa Catalina Island Whiptail lizard) from the stomach of an adult male *C. catalinensis* (TTU 3540; SVL = 770 mm). Additional dissection of the rattlesnake did not produce additional pieces of the lizard. Through direct comparison to specimens of other lizard species from Isla Santa Catalina, we are confident of this identification based on both scalation and size. Our observation adds to the growing list of prey items for *C. catalinensis* and may indicate a more generalist diet. However, it does not support the hypothesis that rattle loss in *C. catalinensis* is for stealth when hunting avian prey in trees, as has been suggested by some authors (Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.; Grismer, *op. cit.*).

We thank the University of Louisiana at Lafayette Department of Biology for providing funding.

***HELICOPS ANGULATUS* (Brown-Banded Watersnake). DIET / SCAVENGING.** Although snakes feed on a wide variety of prey, from small insects to large mammals, scavenging by snakes is poorly documented (DeVault and Krochmal 2002. Herpetologica 58:429–436.; Sazima and Strüsmann 1990. Rev. Brasil. Biol. 50:463–468). Sazima and Strüsmann (*op. cit.*) hypothesized that scavenging by snakes is commonly practiced by opportunistic species, and that low number of observations is probably due to sampling biases. Among the species of snakes known to scavenge dead prey are several aquatic and piscivorous species, but scavenging is not considered a common foraging behavior among neotropical snakes. Neotropical aquatic snakes in the genus *Helicops* are nocturnal and feed mostly on fish, tadpoles and adult frogs (Ávila et al. 2006. J. Herpetol. 40:274–279; Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150), but scavenging has only been documented for *H. modestus* in southern Brazil (Sazima and Strüsmann, *op. cit.*). Herein, we describe an *H. angulatus* scavenging on a rotting *Electrophorus electricus* (Electric Eel) in Ajuruxi basin, Extractive Reserve of Rio Cajari, lower Amazon river, state of Amapá, Brazil.

At 1035 h on 19 December 2011, in aquatic vegetation on the bank of Pelaes stream (0.56218145°S, 51.89035590°W; datum WGS84), we observed an *H. angulatus* attempting to scavenge an *E. electricus* that had recently been killed by a local fisherman. The snake tried to swallow the fish headfirst (Fig. 1), but was unsuccessful, possibly due to the larger size of eel. With our approach, the snake moved into vegetation, leaving the eel on the creek bank. The observation of attempted scavenging by *H. angulatus* is consistent with the hypothesis that scavenging by aquatic and piscivorous species is often overlooked by researchers and may be more common than previously thought (DeVault and Krochmal, *op. cit.*; Sazima and Strüsmann, *op. cit.*).

FIG. 1. *Helicops angulatus* attempting to swallow a rotting *Electrophorus electricus* (Electric Eel) in the Pelaes Stream, Amapá State, Brazillian Amazon.

RAIMUNDO NONATO GOMES MENDES-JÚNIOR, Instituto Chico Mendes de Conservação da Biodiversidade, Rodovia JK, km 02, Universidade Federal do Amapá, Macapá, Amapá, Brazil (e-mail: eelectricus@yahoo.com.br); **HUANN CARLLO GENTIL VASCONCELOS** (e-mail: huann.vasconcelos@unifap.br), **THAYS SANCHES GONÇALVES**, Laboratório de Limnologia, Rodovia JK, km 02, Universidade Federal do Amapá, Macapá, Amapá, Brazil; **RAFAEL DE FRAGA**, Coordenação de Pesquisas em Ecologia, Instituto Nacional de Pesquisas da Amazônia (INPA), Av André Araújo, 2936, Petrópolis, 69011-970, Manaus, AM, Brazil (e-mail: rdefraga@gmail.com).

***LAMPROPELTIS CALLIGASTER* (Prairie Kingsnake). DIET.** *Lampropeltis calligaster* preys upon a variety of small burrowing and surface dwelling mammals but also includes birds and their eggs, reptiles, amphibians, and insects in its diet (Werler and Dixon 2000. Texas Snakes. Univ. Texas Press, Austin. 437 pp.). The few snake species reported as prey items have included *Carphophis amoenus*, *Coluber constrictor*, *Lampropeltis triangulum*, and *Crotalus horridus* (Fitch 1978. Trans. Kansas Acad. Sci. 81:354–362). Here I report an attempted predation event, representing a new diet item for *L. calligaster*.

On the afternoon of 14 May 2012, I observed an adult *L. calligaster* (SVL = 98 cm; total length = 117 cm) attempting to subdue a much larger *Pantherophis obsoletus* (SVL = 138 cm; total length = 166 cm) on the edge of a grassland trail in Van Zandt Co., Texas, USA (Fig. 1). On closer examination, the *L. calligaster*

FIG. 1. *Lampropeltis calligaster* (coiled) attempting to subdue a much larger *Pantherophis obsoletus* in Van Zandt Co., Texas, USA.

appeared to be in the process of swallowing the lower jaw of the open-mouthed *P. obsoletus*, but was having difficulty proceeding past the junction of the upper and lower jaw. After 20 min of observation, both snakes were separated and measured. To my knowledge, this predation attempt not only represents the first report of a *P. obsoletus* in the diet of a *L. calligaster*, but is also notable due to the size of the prey.

R. MICHAEL BURGER, 510 VZ County Road 2721, Mabank, Texas 75147, USA; e-mail: ungaliophis@gmail.com.

***LAMPROPELTIS GETULA CALIFORNIAE* (California Kingsnake). ELEVATION.** On 5 and 6 May 2012, we observed two *Lampropeltis getula californiae* at elevations of 1852.3 m and 1850.4 m, respectively, in Southern California. The first, a juvenile female, was found under a rock in pine woodland near Mount Laguna, San Diego Co., California, USA (32.839°N, 116.420°W, datum WGS84). The second, a young male, was found under a rock in grassland sparsely populated by oak trees on Tejon Ranch in the Tehachapi Mountains, Kern Co., California, USA (34.958°N, 118.568°W; datum WGS84). Both snakes were cataloged with photo vouchers at the San Diego Natural History Museum (female, SDSNH_HerpPC_05214; male, SDSNH_HerpPC_05215). Although *L. g. californiae* have been found as high as 2164 m in the eastern Sierra Nevada, they have not been documented above 1676 m in the California mountain ranges south of the Sierra Nevada (Hubbs 2009. Common Kingsnakes: A Natural History of *Lampropeltis getula*. Tricolor Books, Tempe, Arizona. 412 pp.). To our knowledge, our observations represent the highest maximum elevations reported for *L. g. californiae* in Southern California.

We thank Brian Hinds, the North American Field Herping Association (NAFHA.org), and the Tejon Ranch Conservancy for assistance and support.

***LATICAUDA* SPP. (Sea Krait). AVIAN PREDATION.** Sea snakes are conspicuous and locally abundant in many Indo-Pacific coral reefs. The combination of their potent venom, aposematic coloration, and unpalatable taste presumably deters predation (Heatwole 1999. Sea Snakes. Univ. of New South Wales, Sydney. 148 pp.). However, sea snakes (including amphibious sea kraits, *Laticauda* spp.) are susceptible to predation by some large fish species such as Tiger Sharks (Simpfendorfer et al. 2001. Environ. Biol. Fishes 61:37–46; Wirsing and Heithaus 2009. Mar. Ecol. Prog. Ser. 387:287–293). Some marine birds are considered predators of sea snakes (Heatwole 1975. *In* Dunson [ed.], The Biology of Sea Snakes, pp. 233–249. Univ. Park Press, Baltimore, Maryland; Aubret 2006. Herpetol. Rev. 37:93). Because of their reliance on terrestrial activity, *Laticauda* spp. are also considered to be common prey for Sea Eagles, Ospreys, and Reef Herons (Ineich and Laboute 2002. Sea Snakes of New Caledonia. IRD & Mus. Nat. Hist. Nat. Editions. Collection Faune et flore tropicales, Paris. 303 pp.). However, this assumption is based on very few observations in the wild (Leach 1928. Emu 28:20–42; Bauer and Devaney 1987. *In* Van Gelder et al. [eds.], Proceedings of the 4th Ordinary General Meeting of the Societas Europaea Herpetologica, pp. 43–48. Radboud Universiteit Nijmegen, Mijmegen).

In the Maldives during August 2010, one of us (SP) observed a Grey Heron (*Ardea cinerea*) feeding on what appeared to be a *L. colubrina* (Yellow-lipped Sea Krait; Fig. 1). The bird was manipulating the "snake" by the tail, apparently carefully avoiding the head (Fig. 1B). Overall, manipulation (including vigorous shaking) of the prey lasted for a few minutes before the "snake" was swallowed tail first.

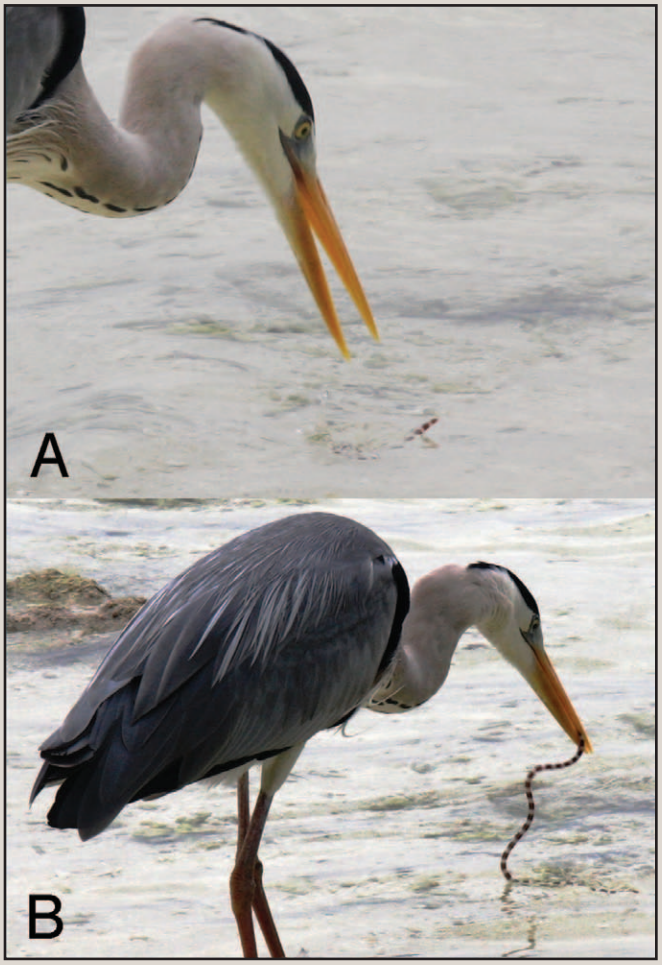

FIG. 1. A) A Grey Heron (*Ardea cinerea*) readies to strike a *Myrichthys colubrinus* (Harlequin snake-eel), which is mimetic with amphibious sea kraits (*Laticauda* spp.). B) The heron manipulates the snake-eel before swallowing.

However, sea kraits are absent from the Maldives. Careful examination of the photographs revealed that the prey eaten by the heron was actually a *Myrichthys colubrinus* (Harlequin Snake-eel) which is mimetic with sea kraits (Randall 2005. Zool. Stud. 44:299–328). Indeed, the similarity between moving (swimming) snake-eels and sea kraits has already misled sea krait specialists (FB and XB, pers. obs.). Although correct identification of *M. colubrinus* is straightforward in still pictures (Fig. 1; see also Randall, *op. cit.)*, differentiation between the mimetic fish and the sea krait is undoubtedly equivocal when the observation is done in the field from a distance. This is especially true if the prey is vigorously struggling to evade predation (Fig. 1B).

Long-term monitoring (2002–2011) of sea krait populations in New Caledonia suggests the absence of avian predation despite the presence of numerous Reef Herons, Ospreys, and large colonies of sea birds (Brischoux and Bonnet 2009. Mém. Mus. Nat. Hist. Nat. 198:133–147). We have never collected any direct or indirect evidence of predation on sea kraits during intensive field work at more than 38 different sites, whereas the birds were

regularly observed preying on fish. Consequently, our observations suggest reappraising avian predation records on sea kraits without a reliable identification of the "snake" prey.

***LEPTOPHIS AHAETULLA* (Giant Parrotsnake). REPRODUCTION.** *Leptophis ahaetulla* is widely distributed from Mexico to Ecuador and northern Argentina, from 0 to 2750 m elevation (Pérez-Santos and Moreno 1988. Ofidios de Colombia. Monografía VI. Museo Regionale di Scienze Naturali Torino. Torino, Italy. 498 pp.). In Costa Rica, *L. ahaetulla* is relatively common in all but the driest habitats and is often observed in bushes and trees in wetlands in tropical and subtropical forests (Solórzano 2002. Serpientes de Costa Rica, Distribución, Taxonomía e Historia Natural. Instituto Nacional de Biodiversidad. Heredia, Costa Rica. 792 pp.). *Leptophis ahaetulla* is known to be oviparous, laying clutches of one to five eggs that hatch during the wet season (May–Nov) after an incubation of approximately 89 days (Solórzano 2002, *op. cit.*; Savage 2002. The Amphibians and Reptiles of Costa Rica: a Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press. Illinois. 934 pp.). However, little is known about courtship and mating behavior in this species.

On 22 January 2006, at 1535 h, we observed a *L. ahaetulla* on the ground in an open area of a private garden in a semi-urban area of Matapalo, Osa Peninsula, Costa Rica (8.39823°N, 83.28219°W, datum WGS84; elev. 240 m). A second individual (male) slowly approached from approximately 3 m away, aligned its body with the first individual (female), and began rolling over the female's body with caudocephalic waves and moving forward across the garden. After 12 min of this behavior, both snakes ascended into a bush (*Croton variegatum*) located approximately 3 m from the first encounter. Over the next 6 mins, the snakes climbed to a height of approximately 1.6 m, at which point they stopped in a position coiled around one another. Intromission occurred for nearly 6 min; afterwards both snakes made coordinated tail-whipping movements with pausing lapses (three times), both in a single movement and always maintaining the same position allowing coitus. This process lasted nearly 8 min, after which a short pause occurred (3 min) and then both individuals dropped to the ground and departed in different directions. No coital neck biting was observed (Gillingham 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. Blackburn Press, New Jersey). The entire process, from the first encounter to the drop-down to the ground, lasted nearly 35 min. To our knowledge, this is the first detailed description of courtship behavior in *L. ahaetulla*. Also, our observation suggests that the mating season for this species occurs at the start of the driest season in the region.

This study was supported by Sierra to Sea Institute and ProCAT International. J.F.G.M. and A.H.E.G. thank the Posgrado en Ciencias Biomédicas, Universidad Nacional Autónoma de México, and Consejo Nacional de Ciencia y Tecnología for graduate study scholarships.

***MASTIGODRYAS BODDAERTI* (Boddaert's Tropical Racer). REPRODUCTION.** *Mastigodrya boddaerti* is a mid-sized snake (average length = 1.5 m) that occurs from Venezuela to Brazil and is common in the eastern region of Pará, Brazil (Cunha and Nascimento 1993. Ofídios da Amazônia. As cobras da região leste do Pará. Bol. Mus. Para. E. Goeldi 9:1–191). On 3 December 2011, we actively searched for herpetofauna around and in the mouth of the Planaltina cave, Pará, Brazil (3.376°S, 52.576°W; datum WGS 84). The area near the cave is secondary forest with a small stream and is surrounded by pastures. Inside the cave we found a nest of five *M. boddaerti* eggs (average length 33.6 mm; range 30.0–39.6 mm) in a wall cavity at 1.5 m above the ground. We visited this nest a month later and four eggs had hatched. We removed and dissected the unhatched egg, revealing a dead neonate (SVL = 214 mm; tail length = 76 mm). This is the first record of *M. boddaerti* nesting inside a cave and provides some of the first reproductive data for the species.

***MICRURUS FULVIUS* (Harlequin Coralsnake). DIET.** *Micrurus fulvius* is known to take a variety of prey items, including lizards: *Plestiodon fasciatus, P. inexpectatus, Neoseps reynoldsi, Ophisaurus ventralis,* and *Scincella lateralis* (Ernst and Ernst 2011. Venomous Reptiles of the United States, Canada, and Northern Mexico, Volume 1, Johns Hopkins Univ. Press, Baltimore, Maryland. 352 pp.). Herein we report a novel prey item for *M. fulvius.*

On 30 March 2005 at 1530 h, JRL and TGJ captured a juvenile female *M. fulvius* (SVL = 470 mm; tail length = 76 mm; 25 g) in a box trap on the Camp Shelby Joint Forces Training Center, Perry Co., Mississippi, USA. The snake appeared to have recently fed due to a large bolus in its stomach and upon palpating, the snake regurgitated an adult male *Anolis carolinensis.* It is possible the *A. carolinensis* was consumed in the trap, and therefore it is unknown how frequently *M. fulvius* will take this species as prey under natural circumstances.

TANYA WALLIN (e-mail: twallin@tnc.org), **JAMES R. LEE** (e-mail: jlee@tnc.org), The Nature Conservancy, Camp Shelby Joint Forces Training Center, CSJFTC-ENV Bldg. 6530, Camp Shelby, Mississippi 39407, USA; **THOMAS G. JACKSON JR.,** 40585 Sierra Drive, Three Rivers, California 93271, USA (e-mail: jacksontg@hotmail.com),.

***NERODIA SIPEDON SIPEDON* (Northern Watersnake). FEEDING BEHAVIOR.** *Nerodia sipedon* is a widely distributed, semi-aquatic snake species that inhabits a variety of lotic and lentic habitats. The diet of *N. sipedon* has been evaluated elsewhere (e.g., Cundall and Pattishall 2011. J. Herpetol. 45:174–177; King 1993. J. Herpetol. 20:90–94), and is known to include a variety of fish and amphibian species (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. Univ. Oklahoma Press, Norman. 437 pp.). Herein we describe a foraging event of *N. s. sipedon* on the Hiawassee River, Polk Co., near Reliance, Tennessee, USA. At approximately 1100 h on 13 August 2011 we observed an adult *N. sipedon* (ca. 1 m total length) retreating from the water with a large (ca. 15 cm total length) River Chub (*Nocomis micropogon*) grasped laterally in its jaws. After exiting the stream, the snake traveled nearly 10 m and retreated tail-first under a small streambank burrow until its entire body was hidden from view. The snake maintained a grasp on the fish, which was folded partially into the burrow.

Although *N. sipedon* has been documented previously as feeding on *N. micropogon* (Gibbons and Dorcas, *op. cit.*), detailed descriptions of prey acquisition have been lacking. Our observation suggests semi-aquatic snakes such as *N. sipedon* use the adjacent streambank as a means to subdue aquatic prey. If a prey item were to escape initial predation attempts within the aquatic environment, it would likely decrease the snake's foraging success. Therefore, it may be advantageous for snakes to move to the terrestrial environment after seizing aquatic prey. Alternatively, retreating to the streambank may serve as an antipredator strategy by which the snake is able to maintain possession of a food item while simultaneously protecting itself from potential predators during the vulnerable period of prey acquisition and processing.

WILLIAM B. SUTTON (e-mail: billsutton.wv@gmail.com), **THAN J. BOVES,** Department of Forestry, Wildlife, and Fisheries, The University of Tennessee, Knoxville, Tennessee 37996, USA; **N. EMILY BOVES,** Ijams Nature Center, Knoxville, Tennessee 37920, USA.

***NERODIA TAXISPILOTA* (Brown Watersnake). DIET.** *Nerodia taxispilota* are known to eat a wide variety of aquatic prey (Holbrook 2012. A Field Guide to the Snakes of Southern Florida. ECO Publ., Rodeo, New Mexico. 225 pp.). Though invasive species have the potential to cause harm to some species, King et al. (2006. Can. J. Zool. 84:108–115) documented a case in which proliferation of an invasive fish was beneficial for Lake Erie Watersnakes (*Nerodia sipeon insularum*). Here we document a novel invasive fish species in the diet of *N. taxispilota*.

FIG. 1. *Nerodia taxispilota* consuming a *Hoplosternum littorale* in Palm Beach Co., Florida, USA.

On 16 May 2012, at Grassy Waters Preserve, Palm Beach Co., Florida, USA (26.80244°N, 80.19479°W; datum WGS84), a small (approx. 25 cm total length) *N. taxispilota* was observed foraging in shallow (~15 cm) marsh habitat. The *N. taxispilota* proceeded to capture and began to consume a *Hoplosternum littorale* (Brown Hoplo Catfish), an exotic species that is well-established in southern Florida (Fig. 1). The *N. taxispilota* consumed the *H. littorale* half way, and then released the meal; likely because it was unintentionally disturbed by the author, not because the food was unpalatable.

JOSHUA D. HOLBROOK, Department of Biological Sciences, Florida Atlantic University, Davie, Florida 33314, USA; e-mail: JHolbro8@fau.edu.

***PYTHON MOLURUS BIVITTATUS* (Burmese Python). HABITAT USE / OCCURRENCE WITHIN *GOPHERUS POLYPHEMUS* BURROWS.** Many native snake species use *Gopherus polyphemus* burrows as a refuge against cold weather conditions, to prevent desiccation, and to assist with shedding (Bogert and Cowles 1947. Am. Mus. Novit. 1358:1–55; Dodd and Barichivich 2007. Florida Sci. 70:83–94; Stevenson et al. 2009. Herpetol. Conserv. Biol. 4:30–42). It has been speculated that the non-native *Python molurus bivittatus* might also use *G. polyphemus* burrows for the same reasons. The discovery of a live *P. molurus* and a shed skin in *G. polyphemus* burrows within Rookery Bay National Estuarine Research Reserve (NERR), Collier Co., Florida, USA, confirms use of this unique habitat by the invasive snake.

On 20 May 2010, I observed a *P. molurus* shed protruding from the mouth of a *G. polyphemus* burrow and extracted approximately 1 m of the shed from outside the burrow and 0.8 m from inside the burrow before it broke off. On 23 Jan 2012, Rookery Bay NERR volunteer Paul Allen tracked and then extracted a live *P. molurus* (total length = 429 cm; 44.4 kg) from a *G. polyphemus* burrow (Fig. 1) approximately 250 m from the previously found shed. The snake was facing towards the burrow entrance and was located approximately 2 m inside the burrow. Tracks indicated that prior to capture, the snake had investigated several other burrows, which it did not enter, before it selected the burrow in which it was captured. The snake appeared to be ready to shed and its selection of this particular burrow, which was smaller than the other burrows, may have been based on size to assist with shedding (Stevenson et al., *op. cit.*). Both the shed and

PHOTO BY RICHARD NADEAU

FIG. 1. Capture of *Python molurus bivittatus* in a *Gopherus polyphemus* burrow at Rookery Bay National Estuarine Research Reserve (NERR), Florida, USA.

the snake were located in palmetto scrub habitat near pine flatwoods and several fresh to brackish water ponds.

The confirmation of burrow use by *P. molurus* raises several important questions. Do *P. molurus* habitually use *G. polyphemus* burrows to prevent desiccation or while shedding (Dodd and Barichivich, *op. cit.*; Stevenson et al., *op. cit.*)? Do *P. molurus* seek underground refugia during cold weather conditions and might this influence their range expansion (Dorcas et al. 2011. Biol. Invas. 13:793–802; Mazzotti et al. 2010. Biol. Invas. 13:143–151)? What effect does burrow use by *P. molurus* have on *G. polyphemus* and burrow commensals?

CHERYL J. METZGER, 3635 Boca Ciega Dr., Naples, Florida 34113, USA; e-mail: metzger_cj@yahoo.com.

***PYTHON MOLURUS BIVITTATUS* (Burmese Python). REPRODUCTION / NESTING.** *Python molurus bivittatus* are reported to nest in mammal burrows, under logs and rocks, and in crevices and vegetation; however, little data exist on their nest structure and characteristics (Snow et al. 2007. Herpetol Rev. 38:93). Here, I report an observation of an abandoned nest of *P. m. bivittatus* from a tea plantation in northeastern Bangladesh.

On 13 May 2011, I found an abandoned nest of *P. m. bivittatus* inside a mammal burrow near Lawachara National Park, Bangladesh (24.330963°N, 091.801120°E; datum WGS 84). Based on information provided by locals, the burrow likely belonged to a porcupine (*Hystrix* sp.). The burrow was located on an east facing slope of a hill (elev. 77 m) in a 12.9-ha cultivated reed (*Imperata* spp., *Phragmites* spp.) grassland, surrounded by tea plantation and tropical mixed-evergreen forests. There were ca. 30 egg shells clustered together in the center. The eggs were unhatched and may have been destroyed by locals. The width and height of the burrow entrance were 44 cm and 30 cm, respectively. The burrow was ca. 268 cm deep on the horizontal plane and the mean width and height were ca. 34 cm and ca. 18 cm, respectively. Notably, on 27 January 2011, two adult *P. m. bivittatus* (female, total length = 414 cm; male, total length = 228 cm) were captured from mammal burrows within 200 m of the abandoned nest. Therefore, it seems that *P. m. bivittatus* in Bangladesh associates with porcupine burrows for breeding and overwintering, similar to *P. m. molurus* in arid regions of western India (Bhupaty and Vijayan 1989. J. Bombay Nat. Hist. Soc. 86:381–387). Despite their tremendous popularity in the pet industry, little is known about the natural history of *P. m. bivittatus* in its native range. Our observation expands our knowledge of python reproduction in Asia.

I thank The Orianne Society and Center for Advanced Research and Natural Management, for funding and logistical support. The field work was conducted under the forest department permit to S.M.A. Rashid (permit: 2M-47/11)

SHAHRIAR CAESAR RAHMAN, Department of Environmental Science, Independent University, Bangladesh; e-mail: caesar_rahman2004@yahoo.com.

***RHINOCHEILUS LECONTEI TESSELLATUS* (Texas Long-nosed Snake). DEFENSIVE BEHAVIOR AND ATTEMPTED PREDATION.** *Rhinocheilus lecontei tessellatus* is a nocturnal constrictor of the dry prairies and deserts (Conant and Collins 1991. A Field Guide to Reptiles and Amphibians: Eastern and Central North America, 3rd ed. Houghton Mifflin, Boston, Massachusetts. 450 pp.). Defensive behaviors of *R. lecontei* include a shifting of coils, twisting of the body, concealment of the head beneath a body coil, and cloacal smearing of blood, feces, and musk gland secretions (Conant and Collins, *op. cit.*; McCoy and Gehlbach 1967. Texas J. Sci. 19:349–352). Here, I report an observation of attempted predation on *R. lecontei* by *Coluber* (=*Masticophis*) *flagellum*. The observation documents a novel predator species and the unusual defensive behavior of knotting for *R. lecontei*.

On 6 May 2001 at ca. 1045 h, I observed a *C. f. testaceus* (total length ca. 125 cm) attempting to prey on a female *R. l. tessellatus* (SVL = 74.7 cm; total length = 84.4 cm) at Lake Alan Henry Wildlife Mitigation Area, ca. 6.5 km N and 14.5 km E of Justiceburg, Garza Co., Texas, USA. The *C. flagellum* had the posterior third of its body wrapped around the base of a prickly pear cactus (*Opuntia* sp.) and was biting the *R. lecontei* near the juncture of the head and neck. The *R. lecontei* was tightly constricted (knotted) around a 26 cm tall clump of dry Broomweed (*Amphiachyris dracunculoides*) adjacent to the prickly pear. The entire *C. flagellum*, except the wrapped tail, and all of the *R. lecontei* were suspended above the ground. This bridged tug-of-war continued without perceived movement for ca. 10 min until I approached and the *C. flagellum* released the *R. lecontei* and retreated. The *R. lecontei* exhibited bite damage dorsally and ventrally, but recovered and was released one week later.

The defensive behavior of knotting is described as a snake wrapping itself around an object or by forming a knot in its body (Yeatman 1983. Herpetol. Rev. 14:22). By knotting around vegetation, the *R. lecontei* established a stalemate and prolonged the predator-prey interaction, potentially increasing the possibility that the predation event would be interrupted and the *R. lecontei* allowed to escape. Knotting may be a widespread defensive behavior in snakes (Hammerson 1988. Herpetol. Rev. 19:85) but has been reported in relatively few species: *Virginia valeriae* (Yeatman, *op. cit.*), *Regina alleni* (O'Brien 1998. Herpetol. Rev. 29:46–47), *Opheodrys aestivus* (Hammerson, *op. cit.*), *Thamnophis crytosis* (Stitt and Swann 2007. Herpetol. Rev. 38:94), and *Boa constrictor* (Guyer and Laska 1996. Herpetol. Rev. 27:203). It is likely that the *R. lecontei* would have been consumed by the *C. flagellum* if the stalemate was not disturbed.

STEPHEN KASPER, Lake Alan Henry Wildlife Mitigation Area, City of Lubbock, Lubbock, Texas 79457, USA (e-mail: skasper@mail.ci.lubbock.tx.us).

***SALVADORA HEXALEPIS* (Western Patch-Nosed Snake). FORAGING BEHAVIOR.** Members of the genus *Salvadora* have an enlarged rostral scale; the function of this "patch" has not been well described, though it may be used to excavate buried lizard eggs (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, DC. 668 pp.). On 08 May 1999, I observed a *S. hexalepis* at Fort Irwin, California, USA (35.1267°N, 116.4962°W, datum WGS84; elev. 650 m). The snake was seen moving slowly and tongue-flicking around the base of a *Larrea tridentata* (Creosote) bush. It stopped near the base of the bush, lifted its head above the ground and forcefully rammed its head into the dirt several times. This movement opened a small hole in the ground. The snake went down into the hole, which apparently led into a subterranean tunnel, and disappeared from sight. As it did so, a small rodent, likely *Perognathus* or *Chaetodipus* sp., emerged from a different hole on the far side of the bush and ran away. The snake eventually emerged from the hole where the rodent appeared. In this apparent foraging attempt, the snake used its snout to directly ram into the soil to expose a likely rodent burrow. Having a larger, thicker rostral scale might be beneficial for this activity.

***STORERIA OCCIPITOMACULATA* (Red-bellied Snake). DIET.** Although it is known that *Storeria occipitomaculata* feeds primarily on slugs (Trapido 1944. Am. Midl. Nat. 31:1–84), there remains a paucity of information regarding the identification of the particular species of slugs involved. Gilhen (1984. Amphibians and Reptiles of Nova Scotia. Nova Scotia Museum, Halifax. 162 pp.) noted that *S. occipitomaculata* in Nova Scotia had preyed upon native *Philomycus carolinianus* (Carolina Mantleslug), as well as non-native slugs in the genera *Arion* and *Deroceras*. Herein, we identify a non-native species of slug in the diet of a *S. occipitomaculata* from northwestern Pennsylvania, USA.

At 0830 h on 11 June 2012, at a site along Hwy 89, 6.2 km SE of Wattsburg, Erie Co., Pennsylvania (41.96156ºN, 79.76165ºW, datum WGS84; elev. 434.3 m), we found a female *S. occipitomaculata* (SVL = 231 mm; total length = 293 mm; 9.5 g) beneath a wooden panel in old field habitat. Upon being handled, the snake disgorged a live *Arion circumscriptus* (Brown-banded Arion), a non-native slug of European origin (Chichester and Lowell 1973. Sterkiana 51:11–42). The slug was 22 mm long, and had a mass of 0.5 g, representing a mass ratio (prey mass to snake mass) of 0.053. *Arion circumscriptus* was present underneath several pieces of debris at the Wattsburg site, and is likely an abundant food source for *S. occipitomaculata* there. Also observed at the site were non-native *Deroceras reticulatum* (Grey Field Slug). The *S. occipitomaculata* was released at the point of capture, while the *A. circumscriptus* was preserved and deposited in the invertebrate collection of the Natural History Museum at the Tom Ridge Environmental Center, Erie, Pennsylvania.

Thanks to George Pisani for reviewing the manuscript.

***THAMNOPHIS PROXIMUS* (Western Ribbonsnake). NECROPHILIA.** Mating or attempted mating with a dead conspecific has been reported in several species of squamates including *Ameiva ameiva* (Costa et al. 2010. Ecologia 3:79–83), *Gambelia wislizenii* (Fallahpour 2005. Herpetol. Rev. 36:177–178), *Holbrookia maculata* (Brinker and Bucklin 2006. Herpetol. Rev. 37:466), *Tiliqua rugosa* (How and Bull 1998. Herpetol. Rev. 29:240), and *Tachymensis brasiliensis* (Amaral 1932. Mem. Int. Butantan 7:91–94). Here, I provide a report of necrophilia in a North American snake species.

At ca. 0230 h on 14 June 2012, I observed what appeared to be a carcass of a dead snake on Navarro Co., Texas, road FM 1129. Upon closer examination, the entwined mass of two courting *T. proximus* became apparent. The smaller snake's head was positioned immediately behind the larger snake's head and appeared to be pressing on the larger snake's dorsum at a downward angle. Caudocephalic waves as described by Gillingham (1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. McGraw-Hill, New Jersey) were observed being performed by the smaller snake, however, it was difficult to ascertain if there was actual cloacal alignment on the closely positioned bodies. As I attempted to move the two individuals off of the roadway, they separated, revealing a live male (total length ca. = 48 cm) and a dead female (total length ca. = 56 cm). The road killed female appeared freshly dead, yet no overt signs of trauma were evident.

***THAMNOPHIS SIRTALIS* (Common Gartersnake). OPEN SEAWATER SWIMMING.** *Thamnophis sirtalis* is common in a myriad of habitats throughout its extensive range in North America (Wright and Wright 1957. Handbook of Snakes of the Unites States and Canada, Vol. II. Comstock Publ., Ithaca. 1055 pp.). Eastern subspecies of *T. sirtalis* are thought to be less aquatic than western subspecies, but all are known to use habitats near or in standing and flowing fresh water (Rossman et. al. 1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman. 332 pp.). Here we report the occurrence of *T. sirtalis* in cold open coastal seawater in Maine, USA.

At 2000 h on 18 August 2009, one of us (EEM), while returning to port aboard a nature cruise vessel, discovered a *T. sirtalis* actively swimming at the surface in Frenchman Bay, Maine. The snake was approximately 3.5 km from Bar Harbor, Hancock County, Maine USA and 150 m from the northern tip of Burnt Porcupine Island (44.24521°N, 068.10717°W; datum WGS 84), Hancock Co., Maine USA. Water depth and temperature were approximately 17 m and 13°C, respectively. Upon capture with a dip net, we noted that the snake (unsexed, total length = 479 mm) was alert, exhibited coordinated body movement, and was free of injuries.

Thamnophis sirtalis are found on a number of offshore islands in Frenchman Bay (Mittelhauser et. al. 1996. Technical report NPS/NESO-RNR/NRTR/96-01, National Park Service, New England System Support Office, Boston. 118 pp.), suggesting that this individual may have dispersed from Burnt Porcupine Island. Whether this snake entered the water of its own volition or was forced in is unknown, but Lillywhite et. al. (2008. BioScience 58:947–955) reported that pit vipers living on Gulf Coast islands occasionally enter seawater, venturing as much as 100 m offshore. Western subspecies of *T. sirtalis* are known to frequent intertidal areas in search of fish prey (Batts 1961. Copeia 1961:350–351), but to the best of our knowledge, this is the first report of *T. sirtalis* swimming in open seawater. Our sighting is also noteworthy from the perspective of snake thermal biology. Nelson and Gregory (2000. J. Herpetol. 34:32–40) found that *T. sirtalis* forage in freshwater as cold as 12.5° C when air temperatures were between 27.0°C and 34.0°C. Although air temperature was not measured in our case, the combination of water temperature, time of day (20 min past sunset), and distance from shore indicate a potentially more challenging thermal environment for snakes to sustain swimming in than that previously reported.

In the first half of the 19th century, with the European discovery of the last of the continents and their colonization of most, natural history museum collections grew rapidly with material obtained from voyages of exploration and new settlements. With the competing colonial aspirations of England and France, the natural history museums in London and Paris in particular rapidly expanded during this period. The herpetological collections in both museums were actively curated and studied, by John Edward Gray in the former case, and André Marie Constant Duméril and his assistant, Gabriel Bibron, in Paris. Both groups commenced herpetological work at about the same time (Gray was first formally employed by the British Museum in December 1824 to prepare a catalogue of the reptiles; Duméril replaced Lacepède as Professor on the latter's death in October 1825, although he had been informally working in that role since 1803, and Bibron was officially employed as Duméril's assistant in 1832, although he had been a student in the laboratory since 1818), and published extensively on their herpetological collections among other activities, but in very different ways. Gray published many of his more extended species descriptions in appendices accompanying the narratives of various exploring expeditions, and restricted his encyclopaedic works, the various Catalogues of the Collection of the British Museum (turtles, crocodiles and amphisbaenians in 1844, lizards in 1845, snakes, in part, in 1849), and an 1831 classification of reptiles accompanying Griffith and Pidgeon's English translation of Cuvier's *Animal Kingdom*, to a more abridged style. Duméril and Bibron, however, largely left the reporting of the natural history collections of the French exploratory expeditions to the naturalists accompanying those expeditions and instead, following a long tradition of French encyclopaedic works on natural history (Buffon's *Histoire Naturelle, Générale et Particulière*, 7 vols, 1785–1791; Cuvier's *Dictionnaire des Sciences Naturelles*, 60 vols, 1816–1830 and *Le Règne Animal Distribué d'après son Organisation*, 4 vols, 1817; the *Nouveau Dictionnaire d'Histoire Naturelle*, 36 vols, 1816–1819; Bory de Saint-Vincent's *Dictionnaire Classique d'Histoire Naturelle*, 16 vols, 1822–1830; Guérin Méneville's *Dictionnaire Pittoresque d'Histoire Naturelle*, 9 vols, 1833–1840; and more specifically herpetologically, Sonnini and Latreille's *Histoire Naturelle des Reptiles*, 4 vols, 1801 and Daudin's *Histoire Naturelle, Générale et Particulière, des Reptiles*, 8 vols, 1801–1803), produced a nine-volume work, the *Erpétologie Générale ou Histoire Naturelle Complète des Reptiles*, aiming to cover the entire knowledge of herpetology. The result was much more thorough than Gray's work (and ultimately more extensive: despite the title mentioning only reptiles, amphibians were included in the *Erpétologie Générale*, whereas Gray left the British Museum amphibians and colubroid snakes to his successor). While Gray covered, for example, the scincid lizards in 64 pages of his Catalogue of the Lizards, recognizing 130 species across 57 genera and 6 families, Duméril and Bibron took over five times that space in 1839, covering the skinks in 326 pages, recognising 96 species in 32 genera, with only one genus in a different family. Not only were Duméril and Bibron's descriptions much more detailed than those of Gray, but their accounts of each order and family were prefaced by extensive biological accounts and thorough bibliographies of the previous literature on the topic, given alphabetically by author and, in the case of systematic studies, chronologically. It is this historical and bibliographic perspective that makes this work so valuable to modern herpetology. However, the *Erpétologie Générale* is not just of value as a review of the older literature. With a large amount of the material being sent to Paris coming from the tropics, both in the Old and New Worlds, many new names were first proposed in these tomes, and as a compilation of knowledge, it formed the major baseline for the next half-century of herpetological systematic studies. Hence, the *Erpétologie Générale* is also an essential and frequently consulted reference for any laboratory working in herpetological systematics.

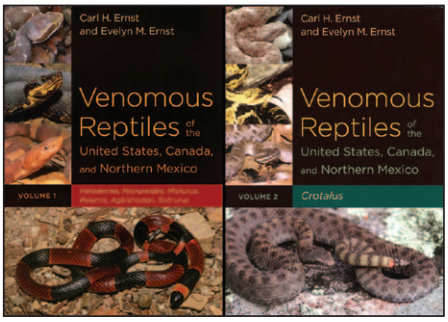
The amount of work involved in producing the 6,600 pages and 120 plates of the *Erpétologie Générale* was enormous, even taking into account the lower known herpetological biodiversity of the era, and Bibron was unable to see the completion of the project, dying of tuberculosis in 1848. With his death, his place as Duméril's assistant was taken by Duméril's son, Auguste Henri André Duméril, and volumes 7 and 9 of the *Erpétologie générale* (the last two volumes published) carry all three names.

The production of this much-awaited facsimile reprint of the *Erpétologie Générale* has similarly been a Herculean task. The largest single facsimile project ever produced by the SSAR, the nine original tomes and atlas are here bound into six handsomely bound volumes (two tomes in most facsimile volumes, with the two parts of Tome 7 constituting a single volume). The first volume begins with an extraordinarily thorough biographical chapter (102 pages) by Roger Bour that provides much new material on the authors and their place in French society of the time, the history of publication of the work and its reception by others, and corrects a number of errors that have been perpetuated in earlier literature on the topic (including, surprisingly, Bibron's date of birth). With Duméril senior in particular also having significant activities in botany, entomology, ichthyology, and medicine (he retained a private medical practice until he was 74, and taught generations of medical students anatomy and pathology), this material will be of broad interest to historians outside of herpetology.

This has clearly been a labor of love for Bour, with the liberal scattering of quotations from contemporary sources, including Duméril's personal letters, and color reproductions of documents and illustrations, combining to give a very personal perspective on the authors' lives. I was particularly struck by the suggestion that Duméril may have inadvertently passed on the smallpox that claimed Lacepède's life through a handshake made after examining patients with the disease—possibly the only case in herpetology of career advancement through killing one's superior.

At the other end of the reprint, Mélanie Pérez, supervised by Bour, and with additional assistance from Kraig Adler, undertook the equally valuable task of creating an extensive index to scientific names that concludes the last text volume, making the information much more accessible (the original largely lacked indices, concluding each tome with a contents listing; the only alphabetic listing, at the end of Tome 9, mixing vernacular and Latin names and only covering genera and higher groups).

The reproduction of the facsimile is of excellent quality. The original text had occasional printing imperfections, varying between copies. These and the inevitable foxing and print-throughs in old books have been fastidiously corrected in the facsimile, making the text as readable as possible, although the scanning is of slightly lower resolution than the original print. The many fold-out synoptic tables in the original are here slightly reduced to fit on facing pages, and inserted (unpaginated, as in the original) in the text. The plates, reprinted here as a single Atlas (the original plates were issued separately in ten parts to accompany the original volumes, in both colored and uncolored versions) are reproduced in both formats on facing pages. This is to allow full details of the plates to be viewed, as the original coloring obscured some of the line details. Although there are some differences in the coloring, in shade, tint and detail, between the facsimile and online scans of two copies of the Atlas on the Biodiversity Heritage Library site (from the Harvard and Smithsonian libraries), these seem to largely reflect individual variation created by the hand coloring of the originals. The vibrant hues of the original plates remain in the facsimile.



The production of a facsimile on this scale is a costly exercise. Luckily, this facsimile was subsidized by a large donation to SSAR by Ronald Javitch, who must be profusely thanked for his generosity. The result is a high-quality facsimile at a bargain basement price for the size of the work. Given the high price of the original at recent sales (two uncolored sets currently available online are priced between US $8000–9000, and even cheap paperback print-on-demand copies cost about US $30 per volume), the limited print run (400 copies) will undoubtedly result in a rapid appreciation of the value of these facsimile sets, so get them while you can.

e-mail: oshea@markoshea.info

There seems to be a long-standing tradition in North American herpetology, especially when it comes to writing books about snakes, for husband and wife co-authorships or publishing collaborations. Examples include Albert and Anna Wright (1957a, b, 1962), Sherman and Madge Minton (1971, 1973), and Roger and Isabelle Conant (1958, 1975). Carl and Evelyn Ernst continued this trend with *Snakes of the United States and Canada* (2003), and they now present their two-volume *Venomous Reptiles of the United States, Canada and Northern Mexico.*

This most recent twin-tome publication is effectively an expansion and update on Carl Ernst's earlier, single-authored, *Venomous Reptiles of North America* (1992), the geographical scope now enlarged to include all "venomous reptiles from the northernmost distribution in southern Canada, through the United States, to 25°N in continental Mexico, the Baja California Peninsula, and those islands in the Gulf of California and off the Pacific Coast of Baja California where they occur" (p. xii). Defining the Baja Peninsula, the islands of the Sea of Cortez and the Mexican islands in the Pacific Ocean, is simple as they exhibit clearly defined natural boundaries, their coastlines, but more difficult must have been the decision how far south to extend the geographical scope of the books in continental Mexico, and how to delineate the southern-most boundaries when no natural feature, like the Rio Grande or a convenient national border, presents itself. The authors ended up using 25°N latitude, which brings all of Sonora, most of Chihuahua and Coahuila, and the northern parts of Sinaloa, Durango, Nuevo Leon, and Tamaulipas under the umbrella of their volumes. But this decision is not without its problems since this is an invisible line with no bearing on the actual distribution of species. Fully 50% of the 34 species included in these volumes have ranges that extend south of

the Latitude 25°N and two of these species (*Agkistrodon taylori* and *Crotalus totonacus*) occur almost entirely south of this line.

Despite their latitudinal cut-off, the authors provide detailed range maps, with the Mexican state borders clearly indicated, illustrating each taxon's entire distribution, into southern Mexico and even Central American countries where necessary. Also included in the species accounts are all the subspecies of these 34 'North American' species whether those subspecies occur within the stated geographical area of the volumes or not. The result is that 13 subspecies with ranges entirely south of 25° N, are included because their conspecifics occur to the north of that line: *Heloderma horridum horridum, H. h. alvarezi, H. h. charlesbogerti, Micruroides euryxanthus neglectus, Micrurus distans michoacaensis, M. d. oliversi, M. d. zweifeli, M. tener fitzingeri, M. t. maculatus, M. t. microgalbineus, Crotalus molossus oaxacus, C. pricei miquihuanus,* and *C. scutulatus salvini*. This is refreshing given that many guides fall back on a phrase such as "four subspecies but only the nominate form is represented within the geographical area of this volume." To their credit, Ernst and Ernst have gone to considerable lengths to include, where possible, as much detail for these extralimital subspecies as those occurring north of 25°N, and in so doing they have increased the value of these two volumes.

The systematic scope of *Venomous Reptiles* is greatly expanded by both its increased geographic area and by taxonomic revisions that have taken place in the twenty years since 1992. The geographical expansion allows the inclusion of northern Mexican species such as *Heloderma horridum, Micrurus distans, Crotalus basiliscus, C. catalinensis, C. enyo,* and *C. tortugensis*, and numerous northern Mexican subspecies of US taxa, such as *Crotalus lepidus, C. ruber,* and *C. willardi*. The taxonomic revisions include the splitting of *Crotalus viridis* into three species (*C. viridis, C. oreganus*, and *C. cerberus*), and the elevation of four former subspecies (*Agkistrodon bilineatus taylori, Micrurus fulvius tener, Crotalus mitchelli stephensi*, and *C. durissus totonacus*) to species. The only taxonomic "loss" might be the synonymy of *Crotalus horridus atricaudatus* within *Crotalus horridus*, as no subspecies are now recognized (Allsteadt et al. 2006). Therefore, this two-volume set includes the same seven genera (*Heloderma, Micruroides, Micrurus, Pelamis, Agkistrodon, Crotalus*, and *Sistrurus*) as the previous volume (Ernst 1992), but with 34 species and 86 subspecies, compared to 21 species and 49 subspecies in the earlier volume.

Of course, taxonomy is an evolving process and field guides and volumes such as these quickly become out of date, albeit by small degrees. New species are described, others placed in synonymy, old names are resurrected, and revisions split long-established taxa. The first to affect the current volumes occurred in the same year as they were published, the resurrection of *Crotalus ornatus* for the Texan populations of *C. molossus* (Anderson and Greenbaum 2012). There is nothing authors can do about this, other changes will undoubtedly follow, but provided the reader keeps up to speed with such advances they do little to detract from the value of the volumes concerned and it will be a further twenty years before a new edition is required to update any changes.

The authors specifically omit the "Rear-fanged (opisthoglyphous) snakes of the Family Colubridae" because North American rear-fanged species have caused only mild envenomings (*Thamnophis, Diadophis* and *Heterodon*), unlike species found in Africa (*Thelotornis* and *Dispholidus*) and Asia (*Rhabdophis*), which have caused fatalities. The authors' decision to omit rear-fanged venomous snakes is completely understandable, it would create another invisible line in the sand, lacking a natural boundary, and to include all rear-fanged North American snakes would greatly expand the size of the volumes and dilute their original purpose.

The content of these two volumes is detailed and comprehensive, as one would expect for two volumes on probably the most studied venomous snake fauna in the world. Volume One begins perfectly logically, not with a section on snake natural history, classification or distribution—a prior knowledge of which is presumably a given, but with sections (they are not numbered chapters) that go straight to the heart of the volumes. The first three sections are titled: Venom, Envenomation by North American Reptiles, and Treatment of Envenomation by Reptiles, so the reader is confronted immediately with the consequences of close encounters with the subjects of the two volumes. The next section concerns itself with the other side of the fence, Conservation of Venomous North American Reptiles, a concept many non-reptile oriented members of the public find hard to comprehend.

There follows a Key to the Families of North American Venomous Reptiles, which might be considered superfluous, as anyone with the slightest knowledge of reptiles can immediately distinguish between the three families represented in these volumes. Surely, more helpful would have been the tools to enable an amateur to separate a milk snake from a coral snake, or a water snake from a cottonmouth. True, as already stated, these volumes are only concerned with front-fanged venomous snakes and venomous lizards, but surely that remit extends to determining whether the snake in the yard is actually a venomous species. The inclusion of a short section explaining the importance of the loreal scale in elapid recognition, and heat-sensitive pits in the pitvipers, and the inclusion of the innocuous colubroid snake families in the key, might have enhanced this section and made it more useful to non-herpetologist readers. In this respect I commend Campbell and Lamar (2004), whose second volume contains an entire chapter on venomous snake mimicry and 237 color plates illustrating venomous snake mimics.

From there the two volumes follow the usual arrangement, with Volume One containing Helodermatidae, Elapidae and the genera *Agkistrodon* and *Sisturus* from the Viperidae, and Volume Two containing the genus *Crotalus*.

The species accounts are excellent, highly detailed and comprehensive, with sections devoted to Recognition, Geographic variation, Confusing species, Karyotype, Fossil Record, Distribution, Habitat, Behavior and Ecology, Reproduction, Growth and Longevity, Diet and Feeding Behavior, Venom Delivery System, Venom and Bites, Predators and Defense, Parasites and Pathogens, Populations, and Remarks. These species accounts are intensively researched and I believe Ernst and Ernst will be the first port of call for anybody wishing to check an unusual prey species, behavioral trait or longevity record for any of the 34 species included in these volumes. For information on North American venomous reptiles it is a one-stop shop, so expect it to be cited on a regular basis in the Natural History Notes section of *Herpetological Review*.

Each species account is also illustrated with grayscale photographs of the species and subspecies concerned, most of them of extremely high quality, as one would expect considering the names in the credits. It is a shame these photographs could not be reproduced in color but the cost of including color images on many if not most pages may have been prohibitive, although the same authors do accomplish this in their earlier volume on the entire snake fauna of the United States and Canada (Ernst and Ernst 2003). Sometimes, however, a grayscale image is more

useful than a color photograph in that detail becomes more apparent, so the fact these images are so reproduced does not detract from the volumes. In fact, if I were to criticize the photography it would be in reference to some of the color plates.

Each volume contains a center section comprising 16 pages of color plates, with two to three plates per page. Some of these plates are excellent but others are of inferior quality, with specimens poorly positioned, too dark with detail obscured, too soft (out of focus) with shallow depth of field, or badly illuminated with stark shadows or color hazes. Many of these images do not do justice to the rest of the books; they look dated and, when one checks back to the earlier volume, it is easy to see why. The 1992 volume contained 32 pages of color plates, equal to the combined total for the 2012 volumes, with 55 individual plates, compared to a total of 76 in the current volumes. Fourteen of these are reused from the earlier volume, in some cases to lesser effect as if the image had been reproduced from a reproduction, rather than the original, with a subsequent loss of quality. This is a shame since some of the color photographs included are excellent, high in detail, well lit, with good depth of field, and with vibrant colors, but the inclusion of a few poor, tired photographs can go a long way to spoil the effect of such high quality images. Given that the North American herpetofauna is probably the most photographed in the world, surely it would have been possible to provide a complete series of new images to enhance these otherwise excellent volumes.

Nit-picking about photography apart, these two volumes are a must-have for anyone interested in the North American herpetofauna, or venomous reptiles and their venoms, and they are likely to grace the shelves of many private and public herpetological libraries. The back cover includes as quote from SciTech Book News: "Likely to remain the standard reference for the next 20 years" and given the impressive content of these two volumes that prediction will probably be proven true.

Cyclura—Natural History, Husbandry, and Conservation of West Indian Rock Iguanas

by Jeffery M. Lemm and Allison C. Alberts. 2011. Academic Press, London (www.elsevier.com). xviii + 221 pp. Hardcover. US $89.95. ISBN 978-1-43-773516-1 (also available in e-book edition for US $70.00).

e-mail: nangeli@tamu.edu

Rock iguanas (*Cyclura*) are among the most threatened groups of lizards (Alberts 2000)—a fact much publicized in conservation media outlets. Despite this, a comprehensive, authoritative book on the genus, to which interested persons could be directed, has so far been lacking. *Cyclura—Natural History, Husbandry, and Conservation of West Indian Rock Iguanas* is the refreshing and much-needed response to this void, a book for the educated public noting the natural history and husbandry of the 16+ species in the genus *Cyclura*. As the greatest threats to rock iguanas are anthropogenic in nature—habitat loss, hunting, mammal predation, etc.—the authors point out in the introduction that this book is intended "…to educate the public on the plight of rock iguanas and the unfortunate demise their populations have suffered at the hands of people and their feral animals." For those interested in a more academic treatment, *Iguanas: Biology and Conservation* (Alberts et al. 2004), stemming from the 1997 "Iguanas: Biology and Conservation" symposium and for which Alberts and Lemm were also key editor/contributors, treats diversity in many more iguanas, including sections dedicated to ecology and conservation.

Cyclura is the kind of book that people can spend hours poring over line by line because it is great fun. I imagine that public libraries, schools, veterinary offices, and eco-lodges will derive great satisfaction from including this scholarly, yet accessible book in their collections.

This book has seven chapters, three of which are contributed (Chapter 1: "Evolution and Biogeography" by Catherine Stephen; Chapter 5: "Nutrition" by Ann Ward and Janet Dempsey; Chapter 6: "Health and Medical Management" by Nancy Lung). The progression that the book makes is mostly natural—wild

rock iguanas and their evolution (Chapters 1–3) is followed by information about husbandry (Chapters 4–6), with a final word on conservation (Chapter 7). Accompanying photographs of species, morphology, and habitat are distracting in the most pleasant way.

Readers are treated in the first chapter, Evolution and Biogeography, to a clear account of the complex island geology and biology of the Caribbean, which follows insular formation from the proto-Antillean landmass (~80–70 MYA) to the present. More than a quarter of the book is dedicated to the second chapter, "Species Accounts," comprising 59 pages devoted to individual accounts for 15 living and one confirmed extinct species, as well as three possible species noted from the fossil record. Each species account includes information on nomenclature, morphology, behavior, and IUCN/CITES/USFWS conservation status. In the species accounts, 'Natural History Notes' synthesize the more important contributions to the scholarly literature. To note, the authors thoughtfully included three labeled diagrams of *Cyclura* scalation and body plan, and a well-planned glossary to guide lay readers through the technical terms in species descriptions.

In the third chapter, "Natural History," the authors supplement current literature with their own observations, providing a comprehensive overview of rock iguanas. For example, 'Diet and Foraging' contains a fascinating description of how rock iguanas use colic nematodes to digest food. The section 'Predators and Defense' builds on the mammalian predation motif from the first two chapters, and includes eye-opening photographs of predators.

The next three chapters (Chapter 4: "Husbandry"; Chapter 5: "Nutrition"; Chapter 6: "Health and Medical Management") could be a great resource for those who keep iguanas or even for those who manage head start programs to share with their volunteers and staff. Importantly, these chapters highlight the paucity of species-specific information. For example, the contributors writing the fifth chapter explicitly state that the lack of diet information on wild rock iguanas is the reason they included fairly general sample diets and supplements appropriate for any *Cyclura* spp. (see Tables 5.3 and 5.4). These chapters also dispel husbandry myths that are not supported in the peer-reviewed literature, such as the belief that gout is induced by high protein diets.

I have just a few complaints with this attractive book. The first is actually a compliment to the authors—the seventh chapter, "Conservation," is a fantastic resource with syntheses of threats, current conservation work, tables of population estimates, and relevant photographs. I believe that it should have been placed much earlier in the book because it shines. It also more appropriately transitions between the wild rock iguana accounts and husbandry content.

Second, wild rock iguana accounts are accessible and informative, but this section desperately needs a distribution map. Flipping back and forth between diagrammatic boxes (see figure 1.3) representing the emergence of Caribbean islands is the only place to contextualize the distribution of *Cyclura* spp. I found myself scanning the whole book several times to see where a map was placed—only to be disappointed. A simple diagram will supplement and vastly improve the species accounts in future editions.

Last, I love glossaries. Everything about a glossary speaks of order and thoughtful preparation of a text. Accordingly, the glossary of ~ 90 terms (pp. 213–215) is well chosen with clear definitions. However, the terms don't include page numbers or warrant space in the index. I recognize that this may be a decision that the publishers made. However, I would argue that it is unlikely a reader is going to make flashcards or study the glossary before using the book. Indexing each term will increase accessibility in a book aimed at a general audience.

Ultimately, the conservation of one of our most lovely iguanid genera depends on exciting the younger generation of herpetological enthusiasts and educating Caribbean tourists. This sort of book, so far outside of traditional books on single topics—either husbandry, or biogeography, or a checklist of species—exhibits the sort of synergy that captivates the public. Non-academics interested in, but unable to find, a soup to nuts account of these charismatic animals are going to be well served by *Cyclura*.

Tadpoles of Africa. The Biology and Identification of All Known Tadpoles in Sub-Saharan Africa

by Alan Channing, Mark-Oliver Rödel, and Jenny Channing. 2012. Chimaira Buchhandelsgesellschaft, Frankfurt am Main, Germany (www.chimaira.de). 402 pp. Hardcover. EUR 49.80 (approx. US$ 68.00) ISBN 978-3-89973-448-5.

Another book. A different book. A must for all people interested in African anurans! There have been a couple of books published in recent years dedicated to Afrotropical amphibians. While, on the one hand, there is a considerable need for new knowledge or summaries of existing information in this field, several of these new books contribute little towards a better understanding of anurans from the African continent. This is certainly not the case with the book by Channing et al. in which the authors have both comprehensively reviewed and organized current knowledge on tadpoles of sub-Saharan African frogs and toads and filled in existing knowledge gaps. As such, the book will become a standard work which will be used for many years. To be

honest, I was initially skeptical about the feasibility of the book and was more than positively surprised how well it succeeds in reaching its goals.

This book justifiably places Africa in a 'pole position' with regard to our understanding of anuran amphibians at the global scale. Certainly, African amphibian diversity in general remains poorly understood and understudied. However, books describing *all* tadpoles in the same manner are still lacking for South America or Asia, regions similarly species-rich and, generally speaking, perhaps better studied.

I very much appreciate the book's structure and how data are presented. Before the species accounts start on page 88, in which tadpoles (as far as this stage exists) of all African anuran genera are described, the authors comprehensively describe the environment in which larval habitats occur, summarize what is known about oviposition and development, and present the reader with an exhaustive chapter on the tadpole bauplan. This is followed by a very informative chapter on (African) tadpole ecology, including information on larval growth to metamorphosis and interactions (both abiotic and biotic) with the environment. The latter topic also encompasses conservation problems like climate change. In an additional chapter, for completeness, Channing et al. also discuss direct development. All chapters are accompanied by high-quality photographs, most of them in color.

In the species account section, about 300 pages long, 365 tadpole descriptions are arranged by family and genus. For each genus, Channing et al. start with a brief introduction and a list of species for which larval stages are unknown. This is perhaps unusual but highlights remaining gaps very well. They then list and describe the known tadpoles, based on either literature information (which is mentioned) or new data. Detailed descriptions are made in a standardized way and follow the following scheme: general information (if applicable), distribution and habitat, morphological description of body as well as of mouthparts. It must be mentioned that the majority of species entries are accompanied by excellent drawings which increase the significance this book even more. Moreover, the authors provide photographs of many tadpoles and their corresponding adults. At the end of the book, the authors attempt to provide keys to aquatic tadpole stages of sub-Saharan African frogs and toads.
I found very few errors or unjustified statements, such as the claim that *Leptopelis mackayi* occurs in the Ruwenzoris of Uganda—there are no published and perhaps not even unpublished records of this species from Uganda. Also, even though literature information is provided in a species entry, it is most useful if the original material examined were also consistently listed (e.g., *Werneria tandyi*). Finally, allocation of larval stages to species is a difficult issue; perhaps the value of the book would have been even higher if the authors had mentioned in each case how tadpoles were assigned to species. These issues, however, are minor and do not detract appreciably from this really impressive volume, which is destined to be a most useful tool for anyone working with African anurans.

Western Pond Turtle: Biology, Sampling Techniques, Inventory and Monitoring, Conservation, and Management

by R. Bruce Bury, Hartwell H. Welsh, Jr., David J. Germano, and Donald T. Ashton (editors). 2012. Northwest Fauna No. 7, Society for Northwestern Vertebrate Biology (www.thesnvb.org). vii + 128 pp., 11 pls. Paperback. US $12.00.

MATTHEW P. BETTELHEIM

Oakland, California 94612, USA
e-mail: matthew.bettelheim@urs.com

After several years in the making, this winter saw the publication of The Society for Northwestern Vertebrate Biology's Northwest Fauna monograph, *Western Pond Turtle: Biology, Sampling Techniques, Inventory and Monitoring, Conservation, and Management* (known informally from its inception as "the western pond turtle handbook"). This handbook marks the culmination of more than 160 years of western pond turtle research since the species was first described (Baird and Girard 1852). It summarizes the state of the species to date, reviewing surveying and sampling protocols, and providing recommendations on species conservation, habitat restoration, and future research needs. Considering that the list of editors (Bury, Welsh, Germano, Ashton) and contributing authors is a veritable who's who in the western pond turtle community, this handbook stands to become a "user's manual" for the species.

The first two chapters are devoted to a brief history and natural history of the species, beginning with a review of nomenclature and taxonomy, a species description, and documentation of the range and distribution between British Columbia and Baja California, followed by a comprehensive summary of western pond turtle biology. The distribution of the western pond turtle throughout its Pacific Coast range illustrated in Figure 1 is a great synthesis of regional distribution databases, including the California Natural Diversity Database, Nevada Department of Wildlife, Oregon Biodiversity Information Center, and Washington Department of Fish and Wildlife.

The bulk of the handbook, chapters 3 through 7 and the associated appendices, are devoted to a review of surveying and sampling protocols. First the authors begin by walking a would-be-researcher through sampling design considerations to help identify the possible constraints and opportunities of a study. Then, the authors tap into standard survey methodologies loaded with a dose of their personal experience garnered collectively through untold years of experience to demonstrate how the techniques can be tailored to studying the western pond turtle. These include everything from visual encounter surveys (western pond turtles are particularly wary) to trapping and snorkeling (the best baits)

to nest searching and detecting hatchlings and young turtles (needles in a haystack). Turtle in hand, the authors next review standard field procedures on how to handle turtles and their data: equipment needs, sanitation, veterinary care, measurements (weight, size, age, sex), marking systems, and radiotelemetry.

In closing, the authors dedicate two chapters to the western pond turtle's future. Under the banner of conservation and restoration, the authors describe the need for habitat preservation and restoration, the unknowns surrounding turtle relocation and head-starting, and the multitudes of threats that continue to put the species at risk: wetland and upland habitat loss, urban development and roads, contaminant spills and pollution, and introduction of predators (bullfrogs and largemouth bass) and competitors (red-eared sliders). Recognizing the need for further studies, the authors conclude with a caution against gray literature and a call for additional peer-reviewed, published research. Answering the questions that remain unanswered—species abundance, population trends, geographic variation, habitat requirements, life-history traits, daily and seasonal activity patterns, diet—may be critical to conserving the species in the years to come.

A single misstatement is noteworthy. In describing the nomenclature and taxonomy of the species in Chapter 1, the authors mistakenly state (page 2): "The name 'Western Pond Turtle' appears to have been first used in the *Field Guide to Western Reptiles and Amphibians* (Stebbins 1966)." In reviewing the early literature it would appear that Cooper (1859:292)—not Stebbins—was the first, not only to use the name "western pond turtle" by more than a century, but also to designate any common name for the species. Earlier scientific literature referred to the species by various binomial names only: *Emys marmorata* (Baird and Girard 1852), *Emys nigra* (Hallowell 1854; Gray 1855; Hallowell 1859), or *Actinemys marmorata* (Agassiz 1857; Baird 1858). Over the next century, several other authors referred to the species as the western pond turtle in advance of Stebbins, among them Lord (1866), Gray (1872), Ditmars (1907), Grinnell and Camp (1917), and Storer and Usinger (1963). Although trivial, this nomenclatural precedence establishes the priority for "western pond turtle" (instead of "Pacific pond turtle") as the oldest available name applied, thereby reinforcing its use consistent with recent convention.

This aside, the handbook is nothing short of thorough, concise, and timely as interest in and threats to the species continue to grow, and the need for a coordinated study and census of the species becomes necessary. A 1992 petition to list the western pond turtle as federally Threatened or Endangered was rejected the following year, although today the species remains listed Endangered in Washington, Sensitive-Critical in Oregon, and a Species of Special Concern in California. Proactive research and conservation, as summarized and advocated in this handbook, are critical to prevent or mitigate the possible need to up-list the species in the future.

by Charlotte Sleigh. 2012. Reaktion Books, London (www.reaktionbooks.co.uk), distributed by The University of Chicago Press (www.press.uchicago.edu). Softcover. 208 pp. US $19.95. ISBN 978-1-861-89920-0.

AARON M. BAUER
Department of Biology, Villanova University, 800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA
e-mail: aaron.bauer@villanova.edu

This small volume is the latest herpetological entry in the "Animal Series" from Reaktion Books, which includes the earlier titles *Snake* and *Tortoise*, as well as 48 other, similarly-named books on assorted mammals, birds, fish, mollusks, and arthropods. All books in the series are similar in size, format, and organization. A suitable subtitle for this book might be "a social history of frogs" or "frogs and the human experience."

The Introduction provides a thumbnail sketch of what frogs are and how they live, touching

on feeding, locomotion, skin secretions, larval life, and other topics. It also chronicles the etymology of "frog" and other words used for anurans and notes the difficulty that humans have traditionally had in categorizing frogs among other vertebrates. Seven chapters follow, each examining a particular theme in the frog-human relationship.

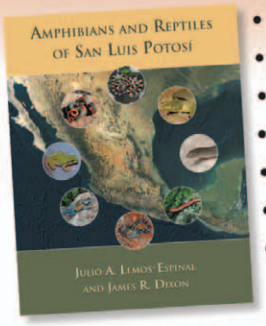
"Just a Kiss" considers the story of the Frog King and similar tales. "Warts and All" looks at the negative connotations of frogs, for example their image as "unclean" animals, plagues of frogs, and their role in witchcraft. "Them, Us, and Frogs" relates frogs and frog-eating to various concepts of national identity. Most English speakers will be familiar with the term "frog" as a derogatory term for the French, but readers may be surprised to learn that in England it was previously used as a slur against the Dutch—until William III, Prince of Orange, invaded England and took the throne, at which time it became politically expedient to apply the epithet elsewhere. This chapter also considers the cane toad and its successful invasion of Australia in light of both that country's national psyche and biosecurity.

"Under the Knife" extolls the role of frogs in medical and other research from Boyle and Swammerdam to the present. "Evolution on Fast-forward" discusses frogs in evolutionary biology and related fields, touching on Ernst Haeckel's biogenetic law, Wilhelm Roux's embryology, the role of *Xenopus* in pregnancy tests, and the well-known "Case of the Midwife Toad" that ended Paul Kammerer's career (and life). The sex life of frogs, and the association of frogs with fertility, rain, luck, and wealth in cultures from ancient Egypt to modern China is the subject of "Of Frogs and Fruitfulness." Lastly "Jumped Up" celebrates frogs as humorous or hapless characters in literature (e.g., *The Celebrated Jumping Frog of Calaveras County*, *The Wind in the Willows*) and popular culture (Michigan J. Frog, Kermit the Frog, the Budweiser frogs) and contrasts this with the current plight of frogs and other amphibians due to a variety of causes, most notably chytridiomycosis.

The book is rounded out by a Timeline of the Frog (with 23 highlights from the origin of frogs to the making of the animated movie *The Princess and the Frog* in 2009), a listing of more than 100 References and a separate Select Bibliography, a list of Associations and Websites, Acknowledgements, and a four page Index to scientific names, people, and subjects. Oddly the "References" are numbered sequentially within chapters but these numbers do not correspond to specific locators in the text (they do in *Snake* and *Tortoise*).

Entertaining though the text is, what really makes this book appealing are its 100+ illustrations, most in color. These include images taken from illuminated manuscripts to classic printed works such as Roessel von Rosenhof's *Historia Naturalis Ranarum Nostratium* with a smattering of magazine covers, political cartoons, television and movie stills, and photos of frog statues, textiles, and jewelry, as well as numerous portraits of photogenic frogs.

There are some oversimplifications regarding anuran systematics and biology and a few minor errors that may be forgiven, since the author is a historian of science, not a herpetologist. Some names are inconsistently used (e.g., *Rana* instead of *Lithobates* for the American Bullfrog, but *Pelophylax* not *Rana* for the European pool and marsh frogs). The claim that frogs were included among reptiles until the mid- to late 19th century is exaggerated. Although some herpetologists used the vernacular term "reptiles" (and others used "amphibians") for both groups of organisms until late in the century, Henri de Blainville formally separated the classes from one another in 1816. On p. 29 an "unidentified blue and yellow frog" is in reality *Phyllomedusa bicolor* and the work it is from is *De Rana Bicolore* by Peter Boddaert (1772). An image on p. 35 is stated to be from the 20th century, but it is from the early 19th century (the date 1825 is even visible on the plate itself). Images of dendrobatids on pages 23 and 24 are transposed relative to their captions and a photo of a ranid on p. 137 is misidentified as *Xenopus laevis*. Finally, at least in my review copy, the text on p. 201 is a duplication of that on the lower two-thirds of p. 200.



The handful of minor complaints aside, this is an inexpensive and attractive little book that can be enjoyed by anyone with a soft spot for frogs, an interest in history, or a love of literature, art, or popular culture. Although herpetologists are unlikely to learn much about their study organisms, they will surely find something new and interesting in this book.

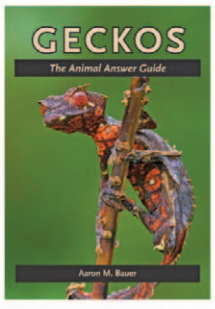
Frogs of the United States and Canada



Two-volume set

C. Kenneth Dodd Jr.

From tree frogs to terrestrial toads, this comprehensive resource offers an unparalleled synthesis of the biology, behavior, and conservation of frogs in North America. Full species accounts for all frogs north of Mexico make this the amphibian book of the decade.

$180.00 hardcover • $180.00 ebook

Geckos

The Animal Answer Guide

Aaron M. Bauer

"This book is recommended if you are considering getting a gecko for a pet or if you just want to know more about the ecology and behavior of the 1,400 or so living species of these peculiar lizards."
—Whit Gibbons, *Aiken Standard*

$26.95 paperback • $26.95 ebook

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

REPRINTS AND PAGE PROOFS

Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not prepared for natural history, geographic distribution, or herpetoculture notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. High resolution electronic (pdf) reprints of notes, articles, book reviews, and obituaries are provided at no charge to the primary/corresponding author as a benefit of SSAR membership. Reprint files will normally be sent prior to the issue mailing date from the printer. Authors who are not current SSAR members may purchase pdf reprints from the SSAR Publications Office.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at the Department of Natural Sciences, Williams Baptist College, P.O. Box 3692, Walnut Ridge, AR 72476, USA. Periodicals postage paid at Walnut Ridge, AR 72476 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.

POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive prepublication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1–880	check website below for current pricing
INDEX TO ACCOUNTS 1–400: Cross-referenced, 64 pages	$6
INDEX TO ACCOUNTS 401–600: Cross-referenced, 32 pages	$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)	$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)	$35
INCOMPLETE SET: NUMBERS 1–190	$75
191–410	$85
411–840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its bulletin, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:
http://www.ssarherps.org/pages/membership.php

Future Annual Meetings
2013 — Albuquerque, New Mexico, 10–15 July (JMIH with ASIH, HL, and AES)
2014 — Chattanooga, Tennessee, 30 July–3 August (JMIH with ASIH, HL, and AES)
2015 — Lawrence, Kansas 30 July–3 August (SSAR with PARC and KHS)

ABOUT OUR COVER: *Lithobates areolatus*

The Crayfish Frog (*Lithobates areolatus*) is a large ranid native to the central United States. Along with the related gopher frogs (*L. sevosus* and *L. capito*), it is among the most fossorial of all North American ranids. This species is of conservation concern throughout most of its range. However, until recently very little was known about its biology other than its breeding season, some aspects of its life history, and that throughout most of its range it primarily uses burrows constructed by large crayfish as refugia outside of the breeding season. Recent studies have shed considerable light on additional aspects of its biology. Perhaps most innovative were studies of Crayfish Frog spatial ecology, as well as the use of passive "trail cameras." These studies documented that individual Crayfish Frogs return to specific burrows or home areas after traveling long distances to and from their breeding ponds, and then once there, they remain nearly sedentary for the remainder of their active seasons (Hoffman et al. 2010. BioScience 60:829–834; Heemeyer et al. 2012. Journal of Wildlife Management 76:1081–1091; Heemeyer and Lannoo 2012. Copeia 2012:440–450).

Our cover depicts a Crayfish Frog from Williamson County, Illinois, in a typical posture outside of a crayfish burrow. The image was taken in 2002 with a Canon EOS A2E film camera, Canon 20–35mm lens, mounted on a Bogen Tripod. Exposure was f/16 at 15 seconds, recorded on Fujichrome Provia 100F slide film. A hand-held Canon 540-EZ flash (using the front-curtain synchcronization function) was used to correctly expose the frog at the beginning of the exposure, while the long total exposure accurately captured the colors of the late dusk sky).

The photographer, **Michael Redmer**, is a biologist with the US Fish & Wildlife Service's Chicago Illinois Field Office. Before joining the Fish & Wildlife Service, Mike worked on demography and reproductive ecology of several species of anurans in Illinois, including *L. areolatus*. This resulted in several publications on those species, including the species account for *L. areolatus* (co-authored with Matthew Parris) in the 2005 book "Amphibian Declines: The Conservation of United States Species," edited by M. J. Lannoo (University of California Press). Experience working with a species associated with crayfish burrows has followed Redmer, who has since 2005 been the USFWS lead biologist for the Eastern Massasauga Rattlesnake (*Sistrurus catenatus*). Mike still dabbles in freelance natural history photography, specializing in portraiture of amphibians, reptiles, invertebrates, and plants.

SSAR BUSINESS

Student Mentorship Program

Attention Student Members! Would you like to have help making the most of attending the Joint Meeting of Ichthyologists and Herpetologists (JMIH, Albuquerque, 10–15 July 2013)?

SSAR will be continuing a mentorship program for undergraduate and graduate students for whom Albuquerque will be their first national meeting. Mentors will be advanced graduate students who have attended JMIH in previous years and who can orient you to the meeting, help make introductions, and enhance your overall meeting experience.

If this is your first meeting, we invite you to apply for a graduate student mentor. We are also accepting applications from graduate students who would be willing to serve as mentors. Applications for both will be accepted during meeting registration.

For more information, please contact: kristinekaiser@gmail.com.

NEWSNOTES

Journal of North American Herpetology— Call for Papers

The Center for North American Herpetology (CNAH) is proud to announce the launch of a new open access, online journal—the *Journal of North American Herpetology* (JNAH). With an impressive cadre of associate editors from all herpetological disciplines, we are now officially soliciting authors for manuscripts and expect to publish the premiere issue by June 2013.

The *Journal of North American Herpetology* provides an open access online venue with the use of all modern digital technologies for peer-reviewed contributions of all aspects of North American herpetology within the geographic boundaries of the United States and Canada. Because of its digital nature JNAH should be able to incorporate relevant video and sound media as well as high-resolution images into articles.

A brief and simple set of instructions to authors as well as a list of topic headings and associate editors can be viewed on the JNAH web page (JNAH.CNAH.org). Questions can be addressed to JNAH.editor@cnah.org. We look forward to your submissions.

—Walter Meshaka Jr. and Dan Fogell

Graduate and Professional Course
Species Monitoring and Conservation: Reptiles

Reptiles is an introduction for graduate students and professionals in wildlife management and conservation to the essential aspects of reptile conservation (both in-situ and ex-situ). It is sponsored by the Smithsonian-Mason School of Conservation, and is to be held at the Smithsonian Conservation Biology Institute, Front Royal, Virginia, USA. The course focuses on the use of field, laboratory, computational, and captive techniques to measure, monitor, and conserve reptile populations. Participants will gain first-hand experience by working with professionals in a variety of settings designed to address current and developing issues in the conservation of reptile diversity.

During the 12-day intensive residential session, participants will learn the principles of study design, develop and carry out field assessments, and use the latest techniques to analyze their data. Practical training in hands-on field techniques, including distance sampling, modern surveillance, trapping, handling and marking methods, sample collection for disease monitoring, and radio-telemetry will be provided by scientists who use these methods as part of their research programs. Participants will also be introduced to use of relevant analytic software, such as DISTANCE, PRESENCE, and MARK, for the application of field-monitoring data to population management and decision making.

Course instructors include experts from the Smithsonian's National Zoological Park (Curator Jim Murphy and Biologist Matt Evans) and National Museum of Natural History, the Virginia Department of Game and Inland Fisheries, the University of Massachusetts, and national and international NGO's. While most instruction takes place on the 3200-acre campus in Front Royal at the newly opened facilities of the Smithsonian-Mason School of Conservation, the course also includes trips to field sites around the region and visits to the National Zoo's Reptile Discovery Center and the National Museum of Natural History's Division of Amphibians and Reptiles, which houses the world's largest curated reptile collection.

The total course fee, which includes instruction and course materials, food, shared lodging, and transport to/from Washington-Dulles International Airport (IAD) is US $3,478. All other travel costs and incidental expenses are the participant's responsibility. Partial scholarships are available on a competitive basis. Participants earn Continuing Education Units; graduate course credit (3) is available for qualified applicants through George Mason University at an additional fee. Participants should have previously completed a college-level basic ecology/evolution course. For first consideration, apply before March 4, 2013. Courses such as this have been full during previous offerings, so you are encouraged to apply early.

Visit http://SMconservation.gmu.edu or contact SCBItraining@si.edu for more information.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

20–23 May 2013—World Crocodile Conference, 22nd Working Meeting of the Crocodile Specialist Group IUCN-SSC, Colombo, Sri Lanka. Information: www.csgsrilanka.com

10–15 July 2013—Joint Meeting of Ichthyologists and Herpetologists (SSAR, HL, ASIH), Albuquerque, New Mexico, USA. Information: http://www.dce.k-state.edu/conf/jointmeeting/

21–25 July 2013—26th International Congress for Conservation Biology, Baltimore, Maryland, USA. Information: http://www.conbio.org/mini-sites/iccb-2013

31 July–3 August 2013—36th International Herpetological Symposium, New Orleans, Louisiana, USA. Information: http://internationalherpetologicalsymposium.com/index.html

22–27 August 2013—SEH 17th European Congress of Herpetology, Veszprém, Hungary. Information: http://seh2013.org/

13–15 September 2013—6th Symposium on the Ecology, Status, and Conservation of Diamondback Terrapins, Seabrook Island, South Carolina, USA. Information: http://www.bio.davidson.edu/terrapin2013/Welcome.html

25–29 September 2013—Annual Meeting of the German Society for Herpetology and Herpetoculture (DGHT), Bonn, Germany. Information: www.dght.de

3–6 October 2013—4th Biology of Vipers Conference, Struga, FYR Macedonia. Information: www.shdmr.org/vipers

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Beck Wehrle or Ben Lowe; e-mail addresses may be found on the inside front cover.

A listing of current contents of various herpetological journals and other publications is available online. Go to: http://www.herplit.com and click on "Current Herpetological Contents."

Insights into the Integumentary Sensory Organs of Crocodylians

Herpetologists have long recognized that crocodilians possess integumentary sensory organs (ISOs), rounded dermal protrusions on their scales. While there is general agreement that they have a sensory function, the exact function of ISOs has been a topic of debate. The distribution of ISOs differs between the two major lineages of crocodylians: in Alligatoridae (alligators and caiman) they are restricted to the head and are densest on the anterior labial regions, while in Crocodylidae (crocodiles and gharials) they are distributed uniformly across the body. The authors of this paper examined the anatomy and physiology of crocodylian ISOs and the feeding behavior of crocodylians with the hopes of illuminating the specific function of these structures. Cross sections through ISOs of both *Alligator mississippiensis* and *Crocodylus niloticus* revealed that they were densely packed with receptors and axons, including receptors within the epidermis, Merkel cell columns directly beneath the epidermis of the ISOs (and absent elsewhere), and lamellated corpuscles (akin to mammalian Pacinian corpuscles) deeper within the dermis. Numerous melanocytes were found immediately beneath the Merkel cells, giving the ISOs their distinctive dark hue. The stratum corneum of the ISOs was 60% thinner than was observed in adjacent skin, which would allow for efficient transdermal perception. In many ways, crocodylian ISOs structurally resembled receptor organs found on the snouts of ducks, monotremes, and moles. For rostral and mandibular ISOs, the afferent neurons lead to the trigeminal nerve. While monitoring extracellular activity near the trigeminal ganglion, the authors stimulated facial ISOs to determine sensitivity and identify "receptive fields" (total area of skin from which a given region of the ganglion receives afferents). This revealed numerous, sometimes overlapping receptive fields, which were smaller anteriorly. Indeed, some of the anterior-most receptive fields comprised a single ISO. The measured threshold of ISO sensitivity ranged from 14 to 0.078 millinewtons (the smallest force that could be experimentally applied). Electrical fields and hypersaline solutions applied to these receptive fields failed to elicit ganglion activity. The authors investigated the ability of these species to locate food without auditory or visual cues, videotaping both species reacting to food dropped into their aquaria under infrared light and white noise. With their ISO-dense labial regions beneath the water, the animals oriented toward water disturbances, but then failed to locate the food until it made physical contact. Upon apprehension, the crocodylians were able to discriminate between edible and non-edible items. Prey-generated water movement did not reliably elicit a response under these conditions. Altogether, these experiments strongly suggest a highly effective mechanoreceptive function for crocodylian ISOs.

Interesting Patterns of Anuran Life History Evolution

Frogs exhibit a wide range of early developmental strategies. Many begin as larvae hatched from unattended, underwater eggs and procure their own food (exotrophy). At the opposite end of the parental investment spectrum, some species hatch into miniature versions of adults (direct development) in nutrient-provisioned terrestrial eggs tended by parents. And a great many species display intermediate strategies. The authors of this study aimed to reveal evolutionary patterns of development and parental investment among frogs, and specifically whether certain intermediate strategies are precursors to direct development. They collected life history, climate, and DNA sequence data for 720 anuran species, including representatives from 48 of the 53 families. For indirect developing species, they determined whether the eggs are laid terrestrially or aquatically, if the eggs and/or larvae occur in protected microhabitats (e.g., underside of leaf, bromeliad, isolated pool of water), have parental protection, and whether the larvae are exotrophic or are sustained by maternally supplied nutrients such as a yolk sack (endotrophy). For a subset of these taxa (470), adult female size, egg size, and clutch size were also recorded and tested for correlations with life history characteristics. Using the concatenated molecular dataset, a time-calibrated phylogeny replete with estimates of clade support was constructed using likelihood methods. Upon this tree, ancestral character states for the life history characters were estimated under a likelihood framework and tests were performed to determine if terrestrial ovopositioning, endotrophy, and/or larval development in a protected microhabitat are evolutionary precursors to direct development. This research revealed that terrestrial egg-laying evolved 48 times, with those lineages subsequently evolving direct development eleven times. Interestingly, direct development evolved in aquatic egg lineages almost as many times (eight). There was also evidence for reversals back to aquatic egg laying from terrestrial laying. Neither developing young located in protected places nor endotrophic larvae were supported as precursors to direct development. Generally, egg size was negatively correlated with clutch size, larger females laid larger clutches, and species exhibiting terrestrial ovopositioning or direct development disproportionately practiced parental care. Relative to terrestrially ovopositioning species, aquatic-laying species were found to have significantly larger females, smaller eggs, and larger clutch sizes, and live in cooler, drier places. This last finding is

interesting, suggesting that while terrestrial egg laying frees species from large bodies of water, as this is a wet-climate phenomenon, it is unlikely to lead to arid-adapted species.

Española Island Giant Tortoise Recovery Program a Success

The Galápagos tortoises native to the island of Española (*Chelonoidis hoodensis*) have been in decline since European contact, initially due to human persecution and later to competition with feral goats. By the 1960s the wild population had diminished to two males and twelve females, which were captured for a breeding program at the Charles Darwin Research Station (along with a third male from the San Diego Zoo). Despite a lack of recruitment on the island, these tortoises successfully reproduced in captivity. In unison with goat eradication efforts, regular offspring repatriation efforts were initiated on the Isla Española during the 1970s. A previous microsatellite study of repatriated tortoises failed to find evidence of successful island breeding and found the allelic frequencies to be very different from those of the breeder population. The authors of this paper aimed to determine whether repatriated tortoises have reproduced on the island, the relative parental contributions of the breeder tortoises in the program, and whether there has been differential post-release survivorship based on genotype. They collected tissue samples from the breeding animals, offspring prior to release (2003, 2007), and tortoises encountered on the island (1994, 2003, 2007). These samples were then genotyped for fifteen microsatellite loci. Using these data, the authors assigned parentage to the offspring and calculated indices of genetic diversity. Failure to identify one or both parents was interpreted as island reproduction if all microsatellite alleles occurred within the breeder population (and breeding pool contamination if not). Island tortoise carapace lengths were also measured. While no reproduction between repatriated tortoises was detected in the 1994 sample, the 2003 and 2007 samples contained nine and 50 island-born tortoises, respectively. Indeed, a quarter of the tortoises sampled in 2007 were born on the island. No significant differences between the genotype frequencies of the pre-release and island samples were recovered, indicating that there has not been strong selection against particular genetic backgrounds and that uneven parentage among the breeder tortoises explains the previously reported skewed genetic makeup of island tortoises. Using available release data, a 5% annual mortality rate, a 20 cm. release size, and a 4 cm. annual growth rate, the authors modeled an expected size frequency of island turtles and found it to be highly correlated with the observed size distribution. This lends support to their hypothesis that the observed heterogeneity in size of island turtles is a solely consequence of variable release effort over the years. This study demonstrates that reintroduction efforts can be successful even with a minimal breeding population; the authors suggest the repatriated animals being a single generation removed from wild ancestors was a reason for this success.

Physiological Dynamics of Wood Frog Freeze Tolerance

Among vertebrates, the ability to survive being frozen solid has been most extensively studied in the Wood Frog (*Rana sylvatica* or *Lithobates sylvaticus*) of North America. This species uses glucose to protect cells from freeze damage and while frozen, blood circulation and respiration cease, and metabolism is reduced to modest anaerobic fermentation. Furthermore, it has been shown that frozen frogs catabolize carbohydrates through the winter while sympatric frogs that overwinter underwater primarily burn lipids. The authors of this paper use respirometry methods to determine the metabolic activity of Wood Frogs over a freeze-thaw cycle and in conjunction with field-collected temperature data, model the cost of winter freezing for this species. To calculate metabolic activity, individual frogs were placed in a small, flow-through chamber fitted with a thermometer and the CO_2 content of the air was determined as it exited. CO_2 was monitored while the frogs were slowly cooled from 4°C to -2.4°C, held there for twelve hours, and slowly returned to 4°C. Freeze-thaw cycle parameters and temperature data from data loggers placed in *R. sylvatica* overwintering microhabitats near Ottawa, Canada were used to generate a model to predict nutrient consumption, the freeze-thaw cycle number, and cumulative time frozen experienced by wild frogs. The change in metabolic activity between 3.5 and 1.8°C was calculated, and as this temperature-metabolic rate relationship ("Q_{10}") was high relative to other vertebrate estimates, the authors used a second, lower Q_{10} above a threshold of 4°C. They also conducted analyses to determine how sensitive their model was to particular parameters; these included allowing a third rate of metabolic change once the frog is frozen, and using a single Q_{10}, different rate change thresholds, and different freezing and thawing temperatures. A general relationship of temperature-metabolism was determined and three consistent metabolic rate spikes were observed: during cooling but prior to freezing, immediately after freezing, and during thawing. These periods coincide with increased O_2 consumption but not increased physical activity, indicating that these increases were due to metabolic activity. The authors estimated that Ottawa Wood Frogs undergo roughly 20 freeze-thaw cycles over winter and spend about 7% of the winter frozen; the insulating properties of the leaf litter and snow lead to dramatic departures from ambient temperatures. The sensitivity analyses demonstrated that neither increasing the amount of time frozen nor the number of freeze-thaw cycles had much effect on lipid consumption while the latter greatly increased carbohydrate consumption. The authors conclude that any lipid savings accrued while frozen are offset by the nutrient costs of freezing and thawing, indicating there must be other selective pressures that led Wood Frogs to freeze tolerance. Furthermore, changes in winter snow cover are predicted to drastically alter the overwintering conditions in this species.

Amphibian Species Found to have Ability to Shrink

Though it seems strange, some vertebrate species have the ability to decrease their length when times are tough. This phenomenon has been demonstrated in a few phylogenetically disparate species, including some fish, a couple tortoises, Marine Iguanas, and a shrew. The authors of this paper find evidence for the first shrinking amphibian, the Jollyville Plateau Salamander (Plethodontidae: *Eurycea tonkawae*). This neotenic species inhabits limestone caves and their associated springs and spring runs in a tiny section of the Edwards Plateau of central Texas, where human demands for water and space are leaving little left for its unique fauna. The authors were conducting a mark-recapture study of this species when a severe drought occurred. During this episode the springs ceased flowing for ten months and the salamanders were forced into subterranean retreats, where food availability was more limited. During multiple sampling efforts before, during, and after the drought, measurements of body length and tail-base width (a proxy for condition) were taken. Within-effort recaptures were used to estimate measurement error. The between-capture growth rate data revealed that almost all individuals shrank in both measurements (tail-base width and body length) during the drought and grew after the drought, even when measurement error is taken into account. These data were then subjected to a series of statistical analyses. Analyses of growth rate covariances with period (drought vs. post-drought) and initial size as explanatory variables revealed significant covariance between all comparisons as well as a significant interaction between period and initial size with regard to body length (but not tail-base width). T-tests revealed that the negative growth rates were statistically significant during the drought. Finally, during the drought, the two growth rates were significantly correlated with each other, while neither were correlated with size at first capture. Attempting to narrow down the possible mechanisms responsible for body shrinkage, the authors examined several cleared and stained specimens, revealing that in these salamanders the vertebrae abut one another, leaving little opportunity for cartilage constriction and pointing to bone loss as the source of shrinkage. The authors emphasize that this strange phenomenon is not necessarily adaptive and may simply be a result of energetic stress.

New Insights into Venom Function in a Neotropical Pitviper

The Terciopelo (Viperidae: *Bothrops asper*) of the Neotropics is responsible for a plurality of the venomous snakebites across its distribution. Like that of other venomous snakes, *B. asper* venom is complex. Recent *in vitro* experiments investigating the myotoxic (muscle-damaging) component of the venom revealed that rather than destroying muscle cells outright, *B. asper* myotoxins alters the permeability of the cells, allowing Ca^{2+} to enter while K^{+} and ATP flow out. In this paper, the authors extended this investigation with *in vivo* experiments. Two previously identified myotoxins were isolated from *B. asper* venom. Anesthetized lab mice were then injected with one of the myotoxins and a solution that releases florescent light as it reacts with ATP and subsequently, emitted light was monitored and quantified. As expected, a large signature of ATP presence was detected in the experimental treatments relative to controls. But strangely, delivery of whole *B. asper* venom indicated a much weaker ATP presence. The authors then assayed the venom for enzymes capable of breaking down ATP, as these have previously been identified in other members of the Terciopelo's subfamily (Crotalinae). Indeed, they found nucleotidases capable of rendering ATP into adenosine, a molecule important in homeostasis, signal transduction, and other vital functions when regulated, but capable of inducing hypotension, paralysis, and anticoagulation when not. This discovery is interesting, as adenosine or a similar molecule is present in most snake venoms but not usually those of the subfamily Crotalinae. The obvious benefits of adenosine in the venom cocktail have been noted by previous researchers, and the authors argue that rather than lacking adenosine in their arsenal, *B. asper* utilizes a by-product of the myotoxin's attack on muscle cells (ATP) as the adenosine source. These discoveries could have great benefits for public health and biomedical research.

Population Genetics of an Imperiled Salamander at its Distributional Limit

Salamandra infraimmaculata is a large fire salamander of the Middle East, reaching its southern distributional limit in northern Israel. It is considered threatened throughout its range, with habitat destruction and invasive species thought to be driving forces of imperilment. To elucidate patterns of genetic diversity and connectivity in *S. infraimmaculata* of northern Israel, the authors of this paper collected 475 genetic samples from 20 populations. These populations were divided between two biogeographic provinces: the Galilee region (11), comprising salamander populations considered contiguous with populations to the north of Israel, and Mt. Carmel (9), where salamander populations are presumed to be isolated from those of the Galilee region to the north (separated by naturally or anthropogenically inhospitable

lowlands) and are the species' southernmost populations. They genotyped the samples for ten microsatellite loci and with those data, generated summary statistics, identified genetic structure using the software package STRUCTURE and analysis of molecular variance (AMOVA), and assessed isolation by distance via mantel tests of F_{ST} statistics. They found the Galilee region to be much more genetically diverse, possessing 40 alleles not found in the Mt. Carmel region. Despite the Mt. Carmel populations lacking any unique alleles (indicating recent divergence from the Galilee populations), the STRUCTURE analysis found strong support for two genetic clusters corresponding to the two regions. This is likely due to strong differences in allele frequencies and indicates the regions are separated by a formidable barrier to gene flow. Furthermore, the AMOVA found that in addition to strong regional differentiation, there is also significant genetic structuring between populations within regions and across the sampled distribution (irrespective of regional membership). They also found a significant signal of isolation by distance within the two regions as well as across the sampled distribution, indicating that gene flow is limited at all levels, which is not surprising given the well-documented limited dispersal ability and breeding site fidelity of this species. The authors argue that because of their genetic distinctiveness, the Mt. Carmel populations need to be managed separately from the Galilee populations.

Two Native New Zealand Frogs Evaluated for Susceptibility to *Bd*

New Zealand's native frogs, the four species of *Leiopelma*, together encompass a large swath of anuran phylogenetic diversity, as they likely split from the nearest relatives during the breakup of Pangaea. They are also threatened with extinction due to a number of factors, with all four species occupying a small fraction of their historical distribution and two of the species restricted to near-shore islands and heavily managed sanctuaries. Furthermore, this threat may be understated, as there is evidence that there may be cryptic diversity within this group. Fortunately, recent work demonstrated that one species, *Leiopelma archeri*, seems to be resistant to *Bd*. The authors of this paper set out to determine whether two additional *Leiopelma* species, *Le. pakeka* and *Le. hochstetteri*, also show a resistance to Bd. Importantly, they used a strain of *Bd* cultured from New Zealand frogs, the virulence of which has not previously been evaluated. Individuals of both species were either inoculated using a solution containing a known concentration *Bd* zoospores or not (control), as were several *Litoria ewingii* (Hylidae), an Australian species introduced to New Zealand and known to be susceptible to *Bd* infection. Frogs were inspected daily for pathological symptoms and evaluated weekly for their weight, ability to right themselves, and infection status (determined through standardized swabbing and qPCR). Weight and infection status were also determined prior to inoculation and at termination. Finally, the effects of species membership, initial weight, and mean Bd load on number of weeks *Bd* -positive were investigated using generalized linear model (GLM) methods. While all *Li. ewingii* in the experimental treatment succumbed to *Bd*, none of the inoculated *Leiopelma* did. Average *Bd* load and species membership were the greatest predictors of weeks *Bd* -positive. Though all *Leiopelma* were *Bd* -free by the end of the experiment, all *Le. hochstetteri* were cleared of *Bd* by week eight while the *Le. pakeka* experimental group took until week 13 to do so. Neither species exhibited symptoms specific chytridiomycosis, though the *Le. pakeka* experimental group did lose a significant amount of weight over the experiment relative to controls and sustained that weight loss long after the terminus of the experiment. The authors stress that while these experiments are important and informative, their findings may not translate to natural systems.

OHMER, M. E., S. M. HERBERT, R. SPEARE, AND P. J. BISHOP. 2012. Experimental exposure indicates the amphibian chytrid pathogen poses low risk to New Zealand's threatened endemic frogs. Animal Conservation (*in press*) doi:10.1111/acv.12010.

Snout Ornamentation Evolution in a Sri Lankan Lizard Genus

The lizard genus *Ceratophora* (Agamidae) is endemic to Sri Lanka and consists of five species. Three of these species possess distinct projections on their snout which the other two species lack. A published molecular phylogeny suggests that rostral appendages have been lost or gained three times in this group. This is surprising, as the acquisition of these structures has been infrequent across Squamata. Three equally parsimonious hypotheses of *Ceratophora* rostral appendage evolution have been identified, however DNA sequence data alone is insufficient for evaluating the relative merits of these scenarios. The authors of this paper collected and analyzed morphological data with the goal of shedding light on *Ceratophora* rostral evolution. Available specimens were assigned to a demographic group (male, female, juvenile) and measured for several characters including snout-vent length, jaw length, and rostral appendage length. Some characters might scale differently with total size. Identifying to what degree and within which age classes this allometric growth is occurring allows comparisons between species, where similar patterns of growth would be evidence for homology. Reduced major axis regression (RMA) was performed to identify and quantify allometric growth in these characters. The standardized allometric coefficients generated by the RMA were then included in an analysis of covariance (ANCOVA) with *post hoc* tests to test for differences in allometry between the demographic groups. These analyses revealed that the patterns of rostral appendage growth vary among the three species. Adult males of one species (*C. tennentii*) exhibit positively allometric rostral growth, but unique to this species, the fleshy, fan-shaped rostrum is also present in juveniles. Taken together with the slow movements of this species, crypsis is a more likely explanation for the rostrum

than sexual selection. Males of the earliest-diverging species (*C. aspera*) have a rough, lanceolate appendage longer than that of the females (despite having a smaller body size), suggesting that sexual selection may be at play. Males of the third species (*C. stoddartii*) showed positively allometric jaw length growth while the females exhibited the opposite; this might indicate opposing selection between the sexes. An increased jaw length increases the length of the lip, which is white and visually extends the white lanceolate rostral appendage (automimicry). This would benefit males if there is intrasexual competition but would be a disadvantage for females, as it would make them more conspicuous. Supporting this hypothesis, individual *C. stoddartii* have been observed twitching their appendages while performing an open-mouth display. The authors conclude, based on the differences in rostral appendage development, form, and function that they likely evolved independently in these three species.

Johnston, G. R., M. S. Y. Lee, and T. D. Surasinghe. 2013. Morphology and allometry suggest multiple origins of rostral appendages in Sri Lankan agamid lizards. Journal of Zoology 289:1–9.

Auditory Communication in a South American Turtle

Although turtles have historically been regarded as silent animals, one familiar instance of chelonian vocalization is that of mating tortoises. Other cryptodiran turtles have also been documented vocalizing, including adolescent big-headed turtles (*Platysternon*) and ovopositioning Leatherback Sea Turtles. Recently, an extensive study of the vocal behaviors of an Australian snake-necked turtle (*Chelodina*) identified 17 distinct vocalization types, indicating that pleurodirans are also capable of vocalizing. As part of a larger project exploring the ecology of the species, the authors of this paper investigated the vocal behavior of the Giant Amazon River Turtle (Pleurodira: *Podocnemis expansa*) both in nature and in captivity. Initially, they made audio recordings of groups of turtles (hatchlings, adults, or both) in water-filled aquaria. Then, they performed similar assays in nature, expanding them to include recordings of eggs prior to hatching, and of adult females released on land. Some of these turtles were fitted with radio transmitters prior to release. The authors then used software to measure various acoustic properties of the vocalizations, allowing for them to be categorized. *P. expansa* of all age classes were recorded making low amplitude vocalizations. They were able to identify eleven different vocalization categories, some effectively age-class specific, and some relatively complex. The embryos begin vocalizing hours before hatching, possibly serving to coordinate hatching, allowing for efficient nest escape and predation dilution. In experiments where groups of hatchling and adult *P. expansa* were released near each other, both vocalized (evidenced by the presence of both juvenile- and adult-specific sounds), and the adults approached the hatchlings. Three separate times, transmitter-fitted hatchlings and adults were found swimming together, once almost four kilometers from the release site. The authors suggest these observations are the first evidence for parental care of hatchlings in turtles. Given the low amplitude of the calls, they suggest that for some species, noise pollution should be added to the list of turtle conservation concerns.

Ferrara, C. R., R. C. Vogt, and R. S. Sousa-Lima. 2013. Turtle vocalizations as the first evidence of posthatching parental care in chelonians. Journal of Comparative Psychology (*in press*). doi: 10.1037/a0029656.

New Insights into the Salamander Transcriptome

The ability of salamanders to readily regenerate anatomical structures has been of great interest to researchers investigating the phenomenon of regeneration generally. Particularly, the molecular processes associated with salamander regeneration have garnered much attention. The authors of this study assembled a transcriptome of various tissues undergoing regeneration in Eastern Newts (*Notophthalmus viridescens*). "Transcriptomes" are the RNA molecules collectively occurring at a particular time and place within an organism, and reflect the particular type of activity that is occurring. As genomic resources are lacking for salamanders (their gigantic genomes are mostly to blame), this transcriptome was assembled without a scaffold ("*de novo*"). To accomplish this, the researchers employed cutting-edge methods of nucleic acid characterization (454 and Illumina paired-end sequencing) as well as Sanger sequencing (after reverse transcription, cloning, and PCR amplification). After combining the results from their various methods, the authors identified 120,922 unique transcripts, of which 38,384 were found to be sufficiently similar to known transcripts of other organisms to be considered homologous. Some of these homologs of previously known transcripts were only recovered in tissues undergoing regeneration. Furthermore, roughly 15,000 transcripts were identified as likely coding for proteins, of which 826 did not match known proteins and therefore have the potential to be unique to Caudata. Many of these contain previously unknown protein motifs, indicating they represent undescribed protein families. As they included transcripts isolated from various regions undergoing regeneration, the authors suggest that it is likely some of these novel proteins are involved with the regeneration process. The discovery of these heretofore unknown proteins will undoubtedly motivate further research into their function. Furthermore, the assembly of the transcriptome of *N. viridescens* lays the groundwork for investigating transcript diversity among salamanders.

Herpetological Review, 2013, 44(1), 8–23.
© 2013 by Society for the Study of Amphibians and Reptiles

Best Practices: In the 21st Century, Taxonomic Decisions in Herpetology are Acceptable Only When Supported by a Body of Evidence and Published via Peer-Review

Taxonomy, the scientific process by which natural groups are identified, described, named, and classified is an exciting research pursuit, not only because it makes an indispensable contribution to biodiversity science but, at a more basic level, because it satisfies the human enjoyment of discovery. However, taxonomy has been an area of biological science in which errors, ethical transgressions, and clashes of egos have been particularly vicious and public, harkening back to the earliest days of the binomial system of nomenclature when Linnaeus (1737) named what he considered an insignificant weed (genus *Siegesbeckia*) after Johann Georg Siegesbeck, a contemporary and very vocal critic.

Taxonomy's Impact.—Taxonomy is a fundamental component of biology because it includes the subdiscipline of biology in which organismal groups are defined and named so that they may fittingly be included in the scientific discourse. Only with precise taxonomy can biologists, and those who apply biological principles, communicate effectively (Cotterill 1997). As a consequence, dubious taxonomy undermines the underpinnings of science as a whole, with potentially serious consequences in basic and applied research. As scientists, we are fully accountable for all elements of our research, especially when our findings have broad contemporary applications. This accountability extends to the taxonomies we create or use. We also believe this responsibility includes monitoring the evidence presented as justification for taxonomic decisions. Normally, this is a key function of peer review (McPeek et al. 2009; Perry et al. 2012; Thompson 2010), but when peer review is circumvented, biologists are forced to find other means to protect the integrity of their science.

Taxonomy in Practice.—The problem with taxonomy arises when the data used to create taxonomic decisions are shoddily presented, derive from spurious research, or lack evidence. While it is true that taxonomic decisions invariably require detailed descriptive components, when these descriptions are built into a scientific framework, they strictly conform to the scientific method; the hypothesis tested is the existing taxonomy, and this hypothesis can be falsified and reformulated (Crother 2009). To perform the tasks that should define 21st Century taxonomic science, three main steps are key: (1) Generate hypotheses of group membership (e.g., a species, a clade) or evolutionary relationship (e.g., sister taxa) based on available primary sources (e.g., existing or new collections of specimens including whole animals, tissues, and DNA sequences) and the available literature; (2) test these hypotheses via appropriate, rigorous, and honest analysis of the relevant data; and (3) submit proposed taxonomic decisions (e.g., taxonomic rearrangements, descriptions of new species, elevation of subspecies to species rank) to peer-reviewed journals in the form of manuscripts that present the data and provide a rational justification for the proposed decisions. These three responsible steps constitute the information processing system that helps to ensure that taxon names, taxon concepts, and taxonomic arrangements are properly grounded in evidence.

21st Century Developments.—In the post-2000 explosion of electronic information, the rapid publication and quick dissemination of scientific information have been prominent and generally positive trends across all research fields, including taxonomy. In keeping with these developments, the International Commission on Zoological Nomenclature (ICZN) recently amended several articles of the *International Code of Zoological Nomenclature* (hereafter referred to as the *Code*) to allow publication of nomenclatural acts solely via electronic media (ICZN 2012). However, in addition to diverse online publishing channels, universally available desktop-publishing technology has also made production of high-quality booklets, pamphlets, and even journals easy for anyone. For taxonomists, this trend is both a curse and a blessing. Even as the path to publication has been simplified and the time to publication shortened by the emergence of

reputable, rigorously scientific, peer-reviewed, and well-edited electronic or rapid-print journals (e.g., *ZooKeys*, *Zootaxa*), publishing is no longer a controlled environment and there are outlets where nonscientific and misguided taxonomy is presented as fact. Differentiating between science and non-science in taxonomy is a challenge. The *Official Register of Zoological Nomenclature* (online as ZooBank) is the authoritative ICZN register for nomenclature and can legitimize registered, electronic-only publications (ICZN 2012).

The authors of this paper understand that the right to freely interpret scientific data as it relates to taxonomic decisions must remain inviolate. Furthermore, we acknowledge that as scientists, we identify provisional truths, which are the best approximations of ultimate truths that we are able to produce at the time, and which remain subject to revision and discussion. However, we see a cautionary tale in the manner by which information is disseminated in the fast-paced world of modern science. We have learned that better placed or marketed falsehoods may supplant truths in public perception. Thus, a taxonomic fact can become obscured by nonscientific information, misleading those who are unable to discern whether the information was appropriately generated. To resist such occurrences, the practice of science in general (and taxonomy in particular) first requires adherence to certain standards for generating, analyzing, and disseminating data. Scientists also need to improve information flow regarding matters of taxonomy and nomenclature, and online registration of names (ICZN 2012) may be a suitable first step. While we accept that "bad" taxonomy remains a possible outcome even when researchers follow proper procedure, we feel that it has become necessary to defend taxonomy against misguided, unscientific practices, and to develop a set of principles to guide taxonomic herpetologists in their research, with the intent to promote (to the extent possible) reliable research that contributes to scientific progress.

Does Unscientific Taxonomy Matter?

In herpetology, unscientific taxonomy, under the guise of science, has been presented with increasing frequency in nonprofessional outlets since the year 2000 (Table 1). The many taxon names proposed in these outlets can have serious negative ramifications: they destabilize taxonomy, and in so doing they confound conservation and legislative efforts, medical herpetology, academic processes, grant administration, and the public perception of herpetology as a whole. As a result, the negative practical impact of needlessly destabilizing taxonomy is likely to be more profound than any other type of fraud or error in herpetology.

Information Storage and Retrieval.—The proliferation of superfluous or dubious names can lead to a breakdown in the information storage and retrieval functions of the taxonomy. A change in the name of a genus, for instance, may lead to the establishment of parallel listings for all the species in that genus.

Professional Communication.—Fear of taxonomic piracy, where one author deliberately expropriates the naming intentions of another, creates an atmosphere of mistrust, stifles collegiality, and promotes insular research. In particular, it discourages communication about unnamed taxa, thus delaying research progress and even conservation action (Oliver and Lee 2010).

Bona fide Taxonomic Research.—Unscientific taxonomic acts have several impacts on genuine taxonomic research. For example, scientists are forced to trace unwarranted or bogus taxonomic accounts in potentially hard-to-locate publications during literature inquiries on synonyms, and they must examine type material in potentially difficult-to-access collections. This not only wastes time and resources, it dilutes legitimate taxonomy with unscientific materials. Taxonomists are relegated to "redescribing" valid taxa that were named prematurely in acts of mass naming or in deliberate acts of intellectual kleptoparasitism (e.g., Aplin and Donnellan 1999; Rawlings et al. 2008). Furthermore, graduate students may have to reformulate thesis proposals or thesis conclusions, and their subsequent publications may be redundant. Nomenclature in grant applications may conflict with unscientific taxonomic publications, resulting in needless delays to ascertain the veracity of the information. In addition, institutional managers not well versed in the details of herpetological research may be unable to follow the mix of validly and unscientifically proposed names or classifications.

Applications of Herpetological Taxonomy.—Confusion about names may cause genuine harm in endeavors relying upon accurate taxonomy of organisms. At the broadest scale, taxonomic confusion will increase the taxonomic impediment to characterizing and managing Earth's biodiversity (Wilson 1985, 2004), including the assessment and protection of threatened taxa and the direction of conservation efforts (Georges and Thomson 2010; Georges et al. 2011; Parham et al. 2006; Pillon and Chase 2007). For example, in the case of species protected by CITES or listed in the IUCN Red List of Threatened Species, dubious taxonomic changes may produce loopholes, where species remain protected according to the rules of these lists, but are not recognized by enforcement agencies. Other areas of particular concern include clinical toxinology, especially the production and use of antivenoms as treatment for the bites of venomous snakes (Fry et al. 2003; Williams et al. 2011; Wüster and McCarthy 1996). In the case of clinical toxinology this may literally be a matter of life and death, when name changes spread via media outlets by attention-seeking authors may cause uncertainty among medical personnel as to which antivenom is appropriate in cases where the name of the source snake species has changed (Sutherland 1999). Wholesale nomenclatural changes at the genus level, especially among medically important snakes, must be carefully considered (even when taxonomically justified) because of the confusion that can arise when the names of relevant species become inconsistent with the names quoted on antivenom products.

Science and the Public.—The public perception of and trust in science is eroded when decisions lacking evidence are presented as fact and permeate what is assumed to be a scientific discourse. The often-strident tone of exchanges surrounding unethical and unscientific taxonomic acts (Borrell 2007) further diminishes the entire scientific discipline in the eyes of the public. In cases where unethical behavior involves illegal activities, international relations, or other similarly sensitive dynamics, the resulting backlash can make it more difficult to conduct *bona fide* research even when good science is demonstrably needed for initiatives such as biodiversity management and conservation.

Unscientific Taxonomy, Embodied

We here present two cases to illustrate unscientific practice. These stand out in the herpetological discipline by the sheer number of taxonomic proposals presented, and the manner in which the authors use the *Code* in contravention of the spirit, if not the letter, of the rules. We use these examples as the departure point for a more general discussion of the scientific

TABLE 1. List of herpetofaunal taxa published on or after 1 January 2000 that can be objectively classed as unscientific, non-peer reviewed, misguided in intent or presentation, fraudulent, or lacking evidence. These names *should not be used* in herpetological nomenclature, pending suitable action by the ICZN. Instead, we urge that these names be treated as listed in the column titled Recommendations by reverting to the older name of record, or by another suitable name as indicated. To avoid confusion, in the Recommendation column we list subgenera in parentheses along with the genus name according to standard nomenclatural usage. All other capitalized, italicized names are genera. Where these recommendations are based on previously published taxonomic decisions or errors, citations and explanations are referenced as superscripts and listed at the end of the table. These recommendations are not formal nomenclatural proposals according to articles of the *Code*, but temporary treatments until the ICZN has developed a suitable response to actions of taxonomic vandals.

standards that we think should be met for acceptable taxonomic studies (and their taxonomic conclusions).

Raymond Hoser's Private Taxonomy.—Between January 2000 and September 2012, Raymond Hoser named two superfamilies, one family, three subfamilies, 89 tribes and subtribes, 113 genera, 64 subgenera, 25 species, and 53 subspecies of reptiles, including Old and New World snakes, geckos, skinks, and crocodiles (Table 1). These names constitute 76% of genera and subgenera and 16% of species and subspecies newly proposed for snakes over that time period (Uetz 2012). Hoser's invariably single-authored papers are characterized by a lack of scientific rigor and plagued by a variety of other problems, including: (1) naming of putatively allopatric populations without primary evidence, but listing the current distribution as the sole or primary distinguishing character (e.g., the diagnosis of *Oxyuranus scutellatus barringeri*—Hoser 2002a:47); (2) invention of evidence (e.g., body color of *Oxyuranus scutellatus adelynhoserae* Hoser 2009c, based on a holotype that is actually an isolated head: BMNH 1992.542); (3) repeated description of the same taxon as new (*Leiopython albertisi barkeri* Hoser 2000a = *L. a. barkerorum* Hoser 2009a = *L. a. barkerorum* Hoser 2012b; *Oxyuranus scutellatus barringeri* Hoser 2002a = *O. s. andrewwilsoni* Hoser 2009c); (4) descriptions of new species and subspecies based on morphological aberrations and vague differences in color pattern (e.g., *Acanthophis barnetti* Hoser 1998:24—diagnosed by the absence of raised supraoculars, which is merely an artifact of preservation [WW, pers. obs.], and "heavier dark pigmentation;" *Pseudonaja textilis cliveevatti* Hoser 2012i:38—diagnosed by stating that "each dorsal scale is darker brown tipped"); and (5) harvesting of clades from published phylogenetic studies for description as new genera or subgenera. For example, the division of *Natrix* into three monotypic genera (*Natrix*, *Jackyhosernatrix*, and *Guystebbinsus*) by Hoser (2012aa[1]) stems from the

[1] Due to the large number of works produced by Raymond Hoser in 2012 (N = 45), we continued the enumeration of citations by beginning the alphabet anew. Thus, in addition to Hoser (2012a–z), 19 additional references exist (Hoser 2012aa–as).

recognition of an unsupported branch in Pyron et al. (2011). Even though the use of patronyms in the naming of taxa is not a contravention of the *Code*, Hoser does not coin and assign names for the purpose of scientific need, taxonomic clarity, or improved characterization of biodiversity, but rather for personal reasons, as explained by the author in most of his etymology sections, as well as in several Internet blogs and social media environments. Hoser's genus and species names are all patronyms, and many include the author's surname (N = 43; Table 1) or the names of his relatives, employees, and even pets.

Without exception, Hoser's taxonomic decisions have been published in outlets with evaluation processes that, if they exist, are not designed to safeguard scientific rigor. Most recently, Hoser (2009a–e, 2012a–ac) has published in the *Australasian Journal of Herpetology* (*AJH*), a vehicle produced and mailed by Hoser himself, and primarily geared towards taxonomic articles of which he is the exclusive author and editor. Although the *AJH* masquerades as a scientific journal, it is perhaps better described as a printed "blog" because it lacks many of the hallmarks of formal scientific communication, and includes much irrelevant information (Ross et al. 2012). Examples of the latter include private email messages in their entirety, as well as polemics against taxonomic herpetologists (e.g., Hoser 2001:48–56; Hoser 2009a:3–21, 30; Hoser 2012a:1–34), taxonomic journals (*Zootaxa*; Hoser 2012a:15ff), wildlife officials (e.g., Hoser 2012f:12), and even judges in courts of law (e.g., Hoser 2012i:45). We maintain that *AJH* should not be considered a "public and permanent *scientific* record" and therefore fails a requirement of the *Code* (Art. 8.1.1; emphasis added) in both style and substance. The *AJH* is not a journal in the scientific sense. It is instead personally distributed by Hoser for unscientific purposes, and should therefore perhaps be best classified as advertising.

The Unscientific Taxonomic Contributions of Richard Wells.—The second case of taxonomic malpractice involves Richard Wells, who has a long history of producing scientifically controversial names, beginning with a near-wholesale alteration of the taxonomy of Australian amphibians and reptiles (Wells and Wellington 1983, 1985). Since 1 January 2000, Wells has described one family, 25 genera, seven species, and three subspecies of reptiles in a publication called *Australian Biodiversity Record*, which he alone edits and produces. Whereas some of the observations in these accounts relating to the natural history of particular taxa may qualify as scientific, the taxonomic decisions proposed by Wells (e.g., Wells 2000a–d) are without scientific merit. Like those published by Raymond Hoser, works by Wells follow the basic requirements of the *Code*, yet lack standard taxonomic data: new taxon names are supported by a diagnosis, but no justification is given for the necessity or authenticity of these names beyond the personal opinion of the author, which is often irreconcilable with published evidence (e.g., Wells 2007d). A failure to specify the material examined and a lack of comparisons with related specimens mean that the taxonomic decisions published by Wells are generally unsupported by well-established sources of evidence. This has resulted in the erection of genera based on characters with unsuitably high degrees of variation, as well as the naming of clinal variants as distinct species. In addition, type designations are often vague, precluding identification of the specimens upon which the names are based (e.g., "an adult specimen in the Australian Museum" in the case of both *Elseya jukesi* and *E. dorriani*; Wells 2002a:8). Furthermore, Wells is very active on blogs, where he has repeatedly threatened "taxonomic terrorism" should his proposals not be accepted by practicing taxonomists. In summary, while Hoser and Wells are undoubtedly knowledgeable about reptiles and could potentially make meaningful scientific contributions, both are instead producing unscientific herpetological taxonomy for apparently private purposes, based on vague descriptions, insufficient evidence, misrepresentations, and other forms of malpractice, which are defended aggressively by personal accusations and invective.

A Matter of Process.—Whereas taxonomy is considered to be a scientific endeavor, nomenclature is essentially a tool for taxonomists to stabilize the use of names corresponding to particular taxonomic findings and entities (*sensu* Mayr 1969; Simpson 1961). Nomenclature could be viewed as the language that scientists use to communicate about biological diversity, and effective communication requires the linguistic terms (in this case, taxon names) to be explicit, universal, and as stable as possible (de Queiroz and Gauthier 1994). The *Code* and the rulings of the ICZN safeguard and uphold the rules of nomenclature, but unfortunately these safeguards do not extend to the taxonomic processes by which names are established in the first place. There is currently no system in place by which the ICZN can prevent the establishment of nomenclature, and concomitant classification schemes, based on taxonomy produced by unscientific practices, including instances of "taxonomic vandalism" (Jäch 2007a,b). As ICZN commissioner Douglas Yanega expressed (Yanega 2009:423), "I think the present system by which we name species is not policed effectively and has loopholes and ambiguities. For example, scientific names can be published in journals without peer review. Although that freedom is fine, the reality effectively permits taxonomic vandals to plagiarize others or publish without scientific merit." This is an apt summary of the problems in taxonomic herpetology (and other disciplines) that are the primary focus of this article: instances where the *Code* protects names produced unscientifically, including those without sufficient evidence, justification, or privately published to bypass the peer-review process.

Best Scientific Practices for Publishing Taxonomic Decisions in Herpetology

The following guidelines, loosely modeled after those presented by the Turtle Taxonomy Working Group (2007), are a set of recommendations against which authors of taxonomic decisions in herpetology, editors of journals publishing such decisions, and anyone consulting such publications upon their release, may judge the merits of these taxonomic decisions and the methods by which they were reached. They are not intended to serve as the single binding set of rules for how taxonomic decisions should be reached, presented, and published in herpetology. However, from our point of view, taxonomic decisions that do not adhere to these best practices should be considered inadmissible to the body of scientific knowledge (and its applications).

Governance.—For any taxonomic decision that proposes a new taxon name or a change to an established one, the ultimate authority regarding nomenclature lies with the ICZN and its *Code*. To be acceptable, nomenclatural changes should be proposed not only in accordance with the requirements presented in the articles of the *Code*; they should also adhere to its spirit (as detailed in the *Introduction* to the *Code*) and its ethics (as detailed in the *Code of Ethics* of the *Code*). However, unless the ICZN formally votes on the conservation or suppression of taxon names, academic freedom governs their use and it is a judgment

call of authors, editors, and readers whether a proposed name should be applied. Thus, we uphold the long-standing tradition by which taxonomy will stabilize over time by use and acceptance or invalidation and rejection in the scientific literature.

Stability.—Whereas new species will be named and taxonomic changes will periodically be necessary to reflect improved information on inferred relationships between taxa, it is ideal if taxonomists maintain concordance with existing nomenclature, and thereby retain existing classifications, to the extent possible to preserve the stability of the established system. Preservation of nomenclatural stability is one of the primary objectives of the *Code*, and even though the *Code*'s articles currently do not set stringent constraints on the naming of taxa, the lack of such constraints must not be misconstrued as license to produce taxonomies according to the letter of the *Code* yet in violation of its spirit, as demonstrated by the examples of Hoser and Wells. Taxonomists should favor nomenclatural continuity unless new, strongly supported analyses make changes unavoidable.

Species.—The biological basis for classification lies with elucidating relationships of evolutionary lineages. Thus, underpinning the presentation of taxonomic decisions are data sets that credibly and reliably assert that the group to be named is on an independent evolutionary trajectory. Names of species should not be coined merely to recognize unusual patterns of distribution or even morphology, but to identify biologically cohesive populations with recent common ancestry, no matter their distribution. The burden of evidence is high in such cases.

Higher Taxa.—Taxonomic decisions regarding taxa above the species level require particular care and demand an even higher burden of evidence, because changes in the names of higher taxa can be especially confusing and destabilizing for users of taxon names and classifications. Names of higher taxa should ordinarily only be coined when data sets reliably identify a monophyletic group containing multiple terminal taxa, although not all such clades necessarily require formal recognition. In this regard, the naming of monotypic higher taxa should be avoided as far as possible, because minimal phylogenetic knowledge is conveyed by such arrangements. However, under some circumstances the establishment of monotypic higher taxa may be justified. For example, this may be the case when an existing generic definition cannot be applied to a sister species with highly divergent morphology, which would otherwise be included in the existing genus. In general, naming of monotypic higher taxa should be avoided and names must be based on the currently available evidence irrespective of hypotheses that the taxon could be expanded in the future.

Evidence.—Information gathering in science is a careful and deliberate process, and it requires the best effort possible to produce a transparent chain of evidence based on reproducible methods. Three lines of evidence are generally accepted for the proposal and testing of taxonomic hypotheses. First, novel evidence is obtained through field and laboratory work, involving samples (e.g., whole specimens, animal parts, tissue samples) from known phenotypes collected in nature, with precisely known provenance, and associated with the obligatory documentation. These samples are deposited in institutions where their long-term curation makes them accessible to other researchers for subsequent hypothesis testing (see Cotterill 1997 on the value of biological collections).

Second, evidence should be sourced from existing samples in museum collections or from published information (e.g., GenBank), both of which are ultimately obtained as described above. In the case of museum specimens (or specimens linked to published information) whose provenance is not precisely known, or whose phenotypic characteristics were not detailed well in life, scientists know to exercise due caution to judge the merits of the material they choose to incorporate into a study.

One or (typically) both of these lines of evidence should be required for taxonomic investigations. They act as a base for further research, so that later work does not have to begin the evidence-collection process *de novo*. For example, storage of sequence data in GenBank makes these data readily available online. If no records from publicly accessible genetic databases, backed by suitable voucher specimens, are listed in support of a taxonomic decision alleged to have been derived from DNA sequence data, then the decision should be rejected. In the case of morphological studies, a standard requirement is a list of specimens of a proposed taxon and a list of the comparative material examined, with their unique identifiers (i.e., source collections and catalog numbers); therefore, if these are not cited (Cifelli and Kielan-Jaworowska 2005:651) the proposed taxonomic arrangement should be rejected. In each case, the mandated citation of the evidence ensures reproducibility, which is one of the hallmarks of science (e.g., Popper 1972).

The third line of evidence is the existing scientific literature—the body of knowledge produced prior to a new research effort. Investigation of the literature on the taxonomic group of interest can provide direction and perhaps impose constraints on proposed taxonomic changes.

Taxonomic decisions proposed in the absence of compelling supporting evidence should be inadmissible in science and in applications of scientific knowledge. Likewise, equivocal or weakly supported nodes in phylogenetic trees should not be named. Furthermore, taxonomic decisions are ideally based on consilience of multiple data sets (e.g., morphological, morphometric, bioacoustic, behavioral, molecular). In the case of cryptic species that cannot be discriminated morphologically or behaviorally, support from molecular data (e.g., mtDNA, nucDNA, cytogenetics) is usually required. The burden of evidence rests on the author(s) of taxonomic decisions, and in each paper that contains such a decision the rationale must be explicit.

This discussion of evidence would be incomplete if we omitted the next logical next step scientists should ideally take once compelling evidence about taxonomic relationships becomes available. Unresolved taxonomic inconsistencies can cause confusion and uncertainty in the literature, which is undesirable for scientists in other disciplines who rely on taxonomists for clear guidance on issues of nomenclature and taxon definition. We therefore strongly recommend that authors who present data sets with clear taxonomic implications (e.g., well-resolved and well-supported molecular phylogenies, evidence for undescribed species) follow their evidence to its taxonomic conclusion and add suitable, formal taxonomic proposals to their discussion. Additionally, an 'orphaned' data set may invite such mischief as discussed above.

Publication.—We think that proposals of taxonomic decisions invariably require a quality control assessment (i.e., peer review) by a group of qualified taxonomic herpetologists (i.e., the editors and reviewers of a particular manuscript). Proposals should take the form of carefully prepared manuscripts that outline the evidence leading to a justified conclusion. Their assessment would typically constitute the editorial process of peer-reviewed journals, during which competent scientists prepare reviews of the work. Authors and print or Internet outlets

avoiding this process can readily be identified as working outside the acceptable rules of science and taxonomy.

It is our recommendation that taxonomic decisions and their concomitant nomenclatural changes are only acceptable when published in peer-reviewed scientific journals and after meeting the following criteria: (1) The investigation must follow an appropriate scientific methodology, which has to be presented in a section devoted to methods. (2) The investigation must provide a list of publically accessible specimens examined, including collection catalog numbers. (3) Publication occurs in a regularly published outlet for scientific research (i.e., not a popular science or trade magazine), available via subscription or accessible online. (4) The outlet must be supported by an editorial team (e.g., editor, associate editors) and supervised by an expert scientific panel (i.e., an editorial board), whose identities and professional affiliations are printed in each issue. (5) Ideally, the manuscript is reviewed by at least two individuals and an editor who, by their research and publication record, can objectively be considered experts in the field. (6) The publication is indexed in the *Zoological Record*, the *Science Citation Index*, or future equivalent databases. (7) If published electronically after 2011, the work must follow the parameters defined by the ICZN (2012). We further propose that the herpetological community, perhaps through the well-curated and easily accessible *Reptile Database* or *Amphibian Species of the World* and with oversight from the ICZN, electronically publish an annual list of outlets known to meet the standards above, through which acceptable taxonomic decisions can be published. New journals, or those not included in the initial listing, may follow the proposed criteria to establish a record of publishing scientifically rigorous taxonomic decisions and will be added to the list as warranted.

The Tricky Business of Working with the *Code*

Taxonomy is a unique area of science because it not only requires research (identification, description, and classification) but also bookkeeping (nomenclature). While the investigative activities are governed by the Scientific Method, bookkeeping is governed, to some extent, by the *Code*. This creates the potential for disharmony in an otherwise logical process; this disharmony is what taxonomic vandals exploit.

"*Coded*" *Challenges.*—The *Code* assists taxonomic scientists once their research is completed by providing rules for the proper administration of a name. It is here that the *Code*, grown from a scientific need, fails to adhere to the science it supports. For example, according to Article 13.1.1 of the *Code*, to become available a name must be "accompanied by a description or definition that states in words characters that are *purported to* differentiate the taxon" (ICZN 1999; emphasis added), regardless of the diagnostic utility of these characters or even their existence. Therefore, the inclusion of taxonomic characters in support of a taxonomic decision may, in practice, be viewed as only *pro forma*. Even as taxonomists endeavor to follow the evidence carefully (e.g., by listing the minutiae of species characteristics in descriptions; Mąkol and Gabryś 2005), such evidence is not required by the *Code*! Even though the gatekeepers of taxonomic science (i.e., the editors, reviewers, and users of taxonomy) may require evidence, the omission in the *Code* provides loopholes for the entrenchment of taxonomic vandals. Furthermore, the *Code*'s *Principle of Priority* (Article 23; ICZN 1999) is the dictum that governs the validity of taxon names, whether derived by proper scientific procedures or not. Consequently, taxonomy becomes prone to abuse by authors like Hoser and Wells.

The ICZN is well aware of the problem of taxonomic vandalism and the resulting destabilization of nomenclature, as exemplified above. Commissioners raise the topic regularly, and the Commission is considering how it can help promote nomenclatural stability in the face of such issues in a way that works within the limits of the *Code* and does not curtail academic freedom (E. Michel, ICZN Executive Secretary, in litt.). It is important to recognize that the purpose of the *Code* is to provide for both continuity and stability of scientific names. The *Code* "has one fundamental aim, which is to provide the maximum universality and continuity in the scientific names of animals compatible with the freedom of scientists to classify animals according to taxonomic judgments" (ICZN 1999: Introduction, line 2). Acceptance of unscientific publications, such as those discussed above, extends the freedom to name animals to people not acting as scientists, which violates the spirit of this "one fundamental aim." Although the ICZN has staunchly advocated and defended the *Principle of Priority* regarding taxonomy, exceptions exist for extraordinary circumstances: "The *Code* recognizes that the rigid application of the *Principle of Priority* may, in certain cases, upset a long-accepted name in its accustomed meaning through the validation of a little-known, or even long-forgotten, name. Therefore the rules must enable the *Principle of Priority* to be set aside on occasions when its application would be destructive of stability or universality, or would cause confusion." (Introduction, Principle 4; ICZN 1999). In the case of unscientific taxonomy, the *Principle of Priority* may be set aside due to lack of usage of a taxon name *in scientific publications*. Thus, boycotting the use of unscientific names proposed since 1 January 2000 and adhering to the recommendations we present (Table 1) will eventually permit the ICZN to rule against them, the *Principle of Priority* notwithstanding.

Items for Action

The Line in the Sand.—To defend herpetological taxonomy against unscientific incursions, we propose that the herpetological community, including authors, reviewers, editors, users of taxon names in applications, and other interested parties, set aside and *strictly avoid the use of the taxon names listed in Table 1*. These taxon names (proposed since 1 January 2000) can be objectively categorized as unscientific by the criteria we have presented. Users may follow the recommendations we present in Table 1 until the ICZN concludes its deliberations about countering the effects of taxonomic vandalism.

In practice, we suggest a two-tiered implementation of this proposal. Firstly, texts in which unscientific taxon names originate should only be cited in the scientific literature when a new taxon is being proposed to overwrite the unscientific name. Secondly, in circumstances where it is necessary to cite a text in which an unscientific name originated, authors should not use the unscientific name itself but should include a suitable explanatory statement, such as: "We follow the recommendations of Kaiser et al. (2013) and consider the name proposed by [author, year] for the taxon under investigation unscientific and unavailable."

The rationale for strict adherence to this recommendation is found in the *Code* itself. According to the *Code* (Article 23.9.1–3; ICZN 1999) it is desirable to avoid the use of names that threaten stability even when this reverses the *Principle of Priority*. This is one area of the existing *Code* where ICZN actions can favor the

establishment of names generated within a genuine scientific framework. The *Code* adopts a strict stand against names (including those that could be classed as unscientific) that have not been used in "at least 25 [scientific] works, published by at least 10 authors in the immediately preceding 50 years and encompassing a span of not less than 10 years" (Article 23.9.1.2; ICZN 1999); thus, authors following best practices could legitimately create names that, under strict application of the *Code*, would amount to junior synonyms of taxa named in an unscientific manner. Unscientific names should be boycotted and scientifically sound names should be used in their place; applications requesting the suppression of unscientific names could then be filed with the ICZN after 10 years have elapsed, and the Commission would then be able to enforce the *Code*. Whilst the date of 1 January 2000 as a "line in the sand" is arbitrary, we consider it a suitably clear juncture at which to begin the rigorous defense of taxonomic integrity in herpetology.

Best Practices.—We further propose that the best practices presented above be used as a basis for framing a practical standard for the taxonomic process in herpetology that can be amended and adopted by herpetological societies and the editorial boards of scientific journals.

ICZN Action Against Taxonomic Vandalism.—We applaud the discussions held by the ICZN on how best to curb taxonomic vandalism, and we encourage the Commission to proceed with all due speed in their deliberations. Time is of the essence, especially given the recent emergence of instances (described above) where individuals have flagrantly violated the spirit of the *Code* and have used taxonomic publications as a vehicle to defame and inflict professional harm on those working within ICZN guidelines.

Censure of Taxonomic Vandals.—We further espouse the idea that emerged at the Seventh World Congress of Herpetology, that herpetological societies pass motions of censure against Raymond T. Hoser and Richard W. Wells (and any other agents of similar grievous taxonomic malpractice that may emerge) for their unwarranted and deliberate destabilization of herpetological nomenclature in the absence of evidence and peer review. We apply the term censure in the sense of *Demeter's Manual of Parliamentary Procedure* (Demeter 1969), meaning that these societies express strong disapproval while allowing the opportunity for those censured to subsequently reform. As of this writing, the British Herpetological Society (BHS) and the Deutsche Gesellschaft für Herpetologie und Terrarienkunde (DGHT) have adopted resolutions to censure Hoser and Wells.

The ideas we present have received broad support from herpetological taxonomists and others with an interest in herpetology (see *Acknowledgments*), and the authors have received formal support from the American Society of Ichthyologists and Herpetologists (per email vote taken by the society's Executive Committee), the Australian Society of Herpetologists (per unanimous Annual General Meeting vote), the BHS (per unanimous Council Meeting vote), the Chinese Herpetological Society (per decision by the society's Standing Council), the DGHT (per Peter Buchert, President; Axel Kwet, Vice President; Jörn Köhler, Chief Editor of *Salamandra*), The Herpetologists' League (per Board of Trustees vote), the Societas Europaea Herpetologica (per decision by the society's Council: Claudia Corti, President; Uwe Fritz, Vice President; Anna Rita Di Cerbo, General Secretary; Wolfgang Böhme, Ordinary Member), the Society for Research on Amphibians and Reptiles in New Zealand (per unanimous Annual General Meeting vote), and the World Congress of Herpetology (per Executive Committee vote) to endorse the Point of View presented here. In addition, the Committee of the Herpetological Association of Africa has expressed its opposition to taxonomic vandalism and has endorsed ethically conducted, scientifically sound taxonomic practices similar to those presented in our Best Practices section. The Crocodile Specialist Group also supports our Point of View, specifically the call to avoid the use of taxon names produced by the type of "vanity publishing" perpetrated by Hoser and Wells (Ross et al. 2012).

Last, it is our hope that the model we present here to safeguard herpetological taxonomy (combining best taxonomic practices, ICZN support, self-policing by authors, reviewers, and editors, and society action) may emerge as a workable solution for other zoological disciplines facing similar challenges.

Acknowledgments.—We wish to acknowledge and thank two groups of people, all of whom are united in opposition to the type of taxonomic vandalism we describe. Listed first are those who made time to provide detailed comments and sometimes important new perspectives on the content we present, and who oppose taxonomic vandalism even though some among their number may not agree with every detail of our discussion, and second are those who expressed unequivocal support for our article in its entirety. The first group includes K. K. Adler, W. Böhme, R. M. Brown, F. T. Burbrink, K. de Queiroz, D. J. Gower, M. S. Hoogmoed, I. Ineich, A. Malhotra, R. W. McDiarmid, E. Michel, A. Ohler, P. Uetz, P. P. van Dijk, Y. L. Werner, and D. Williams. The second group (those who have allied themselves with our viewpoint unequivocally) includes A. Allison, K. Arbuckle, M. Auliya, D. G. Barker, A. Barlow, C. L. Barrio-Amorós, W. R. Branch, A. R. C. Britton, D. Broadley, C. A. Brochu, C. K. Carmichael, C. Corti, D. L. Cundall, J. C. Daltry, R. de Lang, A. R. Di Cerbo, C. K. Dodd, Jr., P. Doughty, W. E. Duellman, L. H. du Preez, R. E. Etheridge, R. N. Fisher, U. Fritz, F. L. Franco, B. G. Fry, A. Georges, F. Glaw, D. M. Green, H. Grillitsch, L. L. Grismer, H. F. Heatwole, D. M. Henderson, R. W. Henderson, J.-M. Hero, W. Hödl, T. R. Holtz, D. W. E. Hone, M. N. Hutchinson, V. H. Hutchison, S. R. Isberg, D. Iskandar, J. B. Iverson III, K. Jackson, G. W. Kaiser, J. S. Keogh, A. Koch, G. Köhler, J. Köhler, G. Kuchling, A. Kwet, M. S. Y. Lee, J. D. Lynch, S. Maddock, D. Millar, J. C. Murphy, H. R. Mushinsky, D. Naish, J. F. Parham, W. G. Parker, C. L. Parkinson, S. J. Richards, J. M. Savage, J. D. Scanlon, A. Schmitz, R. Shine, M. Shirley, B. Sidelau, J. W. Sites, Jr., A. Skinner, R. G. Sprackland, M. Solé, S. Thomson, P. Upchurch, S. Ursenbacher, J. van Rooijen, M. Vences, N. Vidal, L. J. Vitt, V. Wallach, G. J. W. Webb, M. J. Wedel, T. Wilms, M. T. Young, and G. R. Zug. We also thank H. B. Shaffer and two anonymous reviewers for their time and expertise. Their insights and comments strengthened the paper considerably.

Anecdote vs. Substantiated Fact: The Problem of Unverified Reports in the Toxinological and Herpetological Literature Describing Non-front-fanged Colubroid ("Colubrid") Snakebites

Non-front-fanged colubroid snakes (NFFC) comprise a diverse group of approximately 2,350 species. Some of these snakes were previously and inappropriately placed together in the family Colubridae. During the last 50 years, increasing attention has been given to the systematics of snakes in this artificial assemblage, and recent investigations have re-assigned a significant number of former colubrid taxa to other families or sub-families (e.g., Lawson et al. 2005; Pyron et al. 2011; Vidal et al. 2007, 2010; Wiens et al. 2008; Zaher et al. 2009). These snakes were previously termed "rear-fanged," "opisthoglyphous," or "aglyphous" "colubrids" in reference to their posterior or mid-maxillary dentition that may or may not have external grooves, but lacks an internal lumen or canal (McKinstry 1983; Weinstein and Kardong 1994; Weinstein et al. 2011).

Envenoming by five species of NFFC (three species of dispholidines and two natricine taxa; see ahead) have proved

to be life threatening and/or fatal in humans, a clear warning that all NFFCs should be handled carefully, some if at all, and that bites should be avoided as much as possible. Among other NFFCs, there is no clear correlation between lethal potencies of venoms/Duvernoy's secretions and risk to humans. The venoms of the aforementioned five species have i.v. murine LD_{50} ranging between 0.05–0.50 mg/kg, while those of the relatively small number of other species studied to date range widely between 2.5–80 mg/kg (see Weinstein and Kardong 1994 and Weinstein et al. 2011, for tabular comparisons of representative NFFC venom/secretion LD_{50}). While these general observations suggest that many common smaller species of NFFC present little medical risk, such assessment must be cautious because of the limited available comprehensive data; some of these can produce significant local morbidity but the vast majority of NFFC have not been studied at all. The composition of NFFC venoms/Duvernoy's secretions is similar to that of venoms of viperids, elapids and *Atractaspis* spp. (Ching et al. 2006; Fry et al. 2003, 2008; Hill and Mackessy 2000; Mackessy 2002; Minton and Weinstein 1987; Peichoto et al. 2012 Weinstein and Smith 1993; Weinstein and Kardong 1994; Weldon and Mackessy 2010), and recent proteomic, genomic and transcriptomic investigations have further characterized or identified a rich array of biologically active constituents including multiple enzymes and isozymes (e.g., metalloproteases, phospholipases A_2, fibrinogenases, Factor X and prothrombin-activators, and others), cysteine-rich secretory proteins (CRISPs), myotoxins, and post-synaptic neurotoxins (Ching et al. 2006, 2012; Estrella et al. 2010; Fry et al. 2003, 2008; Peichoto et al. 2012; Weldon and Mackessy 2010). Although it is likely that some of these contribute to the effects (especially local pathology) observed after some medically significant NFFC bites, to date, the few well-characterized neurotoxins have not had any clear medical relevance as these have shown greater specificity for the motor-end plates of their natural saurian and/or avian prey species (e.g., Pawlak et al. 2006, 2009). Only a single NFFC species (the Montpellier Snake, *Malpolon monspessulanus*) has inflicted a well-documented neurotoxic envenoming. Although a relative handful of toxins present in the oral secretions/venoms and glands of NFFC have been well-characterized, the majority of NFFC produce oral products that have unknown properties and/or functions (Weinstein et al. 2011, 2012). A large number of NFFC species produce oral products that have been termed by some investigators, "Duvernoy's secretions," in reference to the low-pressure gland found in these snakes, although a number of authors call these glands "venom glands," on the basis of established phylogenetic relationships and/or the presence in their glands/oral secretions or tissues of toxins, or their transcripts/genes that are shared among front-fanged snakes, e.g., viperids, elapids, and atractaspidine lamprophiids. This definition notably departs from the traditional consensus that defined venoms by biological function (e.g., active use in acquisition of prey and/or self defense) in addition to toxinological and morphological criteria (Kardong 1996; Mebs 2002; Minton 1974; Russell 1980). Due to unknown or unverified functions of many of these, a relatively small number of these snakes meet the traditional biological criteria defining them as "venomous."

The controversies associated with these terms and the debate over the definition of the terms "venom" and "venomous," have been detailed elsewhere (Fry et al. 2012; Kardong 2012; Weinstein et al. 2011, 2012).

Snake Venoms and Toxic Oral Secretions: Medical Significance ≠ Biological Significance

The biological basis of the traditional perception of venom is commonly confused with medical significance in the popular, and occasionally, in the medical and even scientific literature. From this perspective, the medical effects of snake venoms are a circumstantial result of the interaction of humans with snakes that produce venoms, which coincidentally have a medically significant effect on a human victim. Venomous snakes evolved long before humans and thus their venoms are directed at increasing their likelihood of survival, their fitness, within their hostile and challenging environment, and not for the explicit purpose of being used against humans. Therefore, the medical effects of snake venoms and other ophidian oral products are evolutionarily irrelevant and should not be used as criteria to define snakes that are "venomous" and those that are not.

"Venom" or "Toxic Saliva"?

Although there has been strong interest in the toxic nature of "colubrid" (=NFFC) oral products since the early 19th century, detection or isolation of proteins/toxins commonly found in front-fanged snake venoms from some NFFC oral products ("Duvernoy's secretions," or "venoms") have been reported only since the late 1970s. Throughout the 20th century, there has been confusion regarding how and when to apply the term "venom," or "venomous," to various NFFC. As a specific example also discussed by McKinstry (1983), Cowles (1941) reported the effects of bites inflicted by the Spotted or Coast Nightsnake (*Hypsiglena ochrorhynchus*) on a variety of lizards, and noted that the effects ranged from slight discoloration to death. Goodman (1953) reported delayed (about 2 h) death of a Sagebrush Lizard (*Sceloporus graciosus*) after being "chewed on" by a *Hypsiglena* sp. However, Dundee (1950) reported that a Texas Nightsnake (*H. torquata texana* [*H. ochrorhynchus texana* sensu Mulcahy 2008]) briefly seized a "worm" (blind) snake (*Leptotyphlops* [*Rena* Baird and Girard 1853] sp.) without any observed effect. Therefore, some authors subsequently described *Hypsiglena* spp. variously as "venomous," "non-venomous," "mildly venomous," or, with "saliva" of a "toxic" or "venomous nature." There are similarly inconsistent descriptions in the literature of a significant number of common NFFC. Some trained observers have reported unambiguous use of NFFC oral products that clearly is consistent with the traditional consensus definition of "venom" in that these were actively used in order to subdue prey. Some of these include: the Boomslang (*Dispholidus typus*), African twig, bird or vine snakes (*Thelotornis* spp.), the Tiger Keelback (*Rhabdophis tigrinus*) and Red-necked Keelback (*R. subminiatus*), Green Vine Snake (*Oxybelis fulgidus*), the Ringneck Snake (*Diadophis punctatus*), the Puerto Rican Racer (*Alsophis portoricensis* [*Borikenophis portoricensis* sensu Hedges et al. 2009]) and the Mangrove Snake (*Boiga dendrophila*) (see Weinstein et al. 2011, for a review of these reports). However, there are other species for which to date there is no well-documented evidence of the active, consistent use of oral products in prey capture and/or self-defense, regardless of their experimental toxicity and demonstrated content of toxins common in snake venoms. Some of these species include garter and ribbon snakes (*Thamnophis* spp.), hognose snakes (*Heterodon* spp.), and False Water Cobras (*Hydrodynastes gigas*). As noted previously, there are a very large number of NFFC taxa (in fact, the majority of the approximately

2,350 species) that have oral products with unknown properties and function.

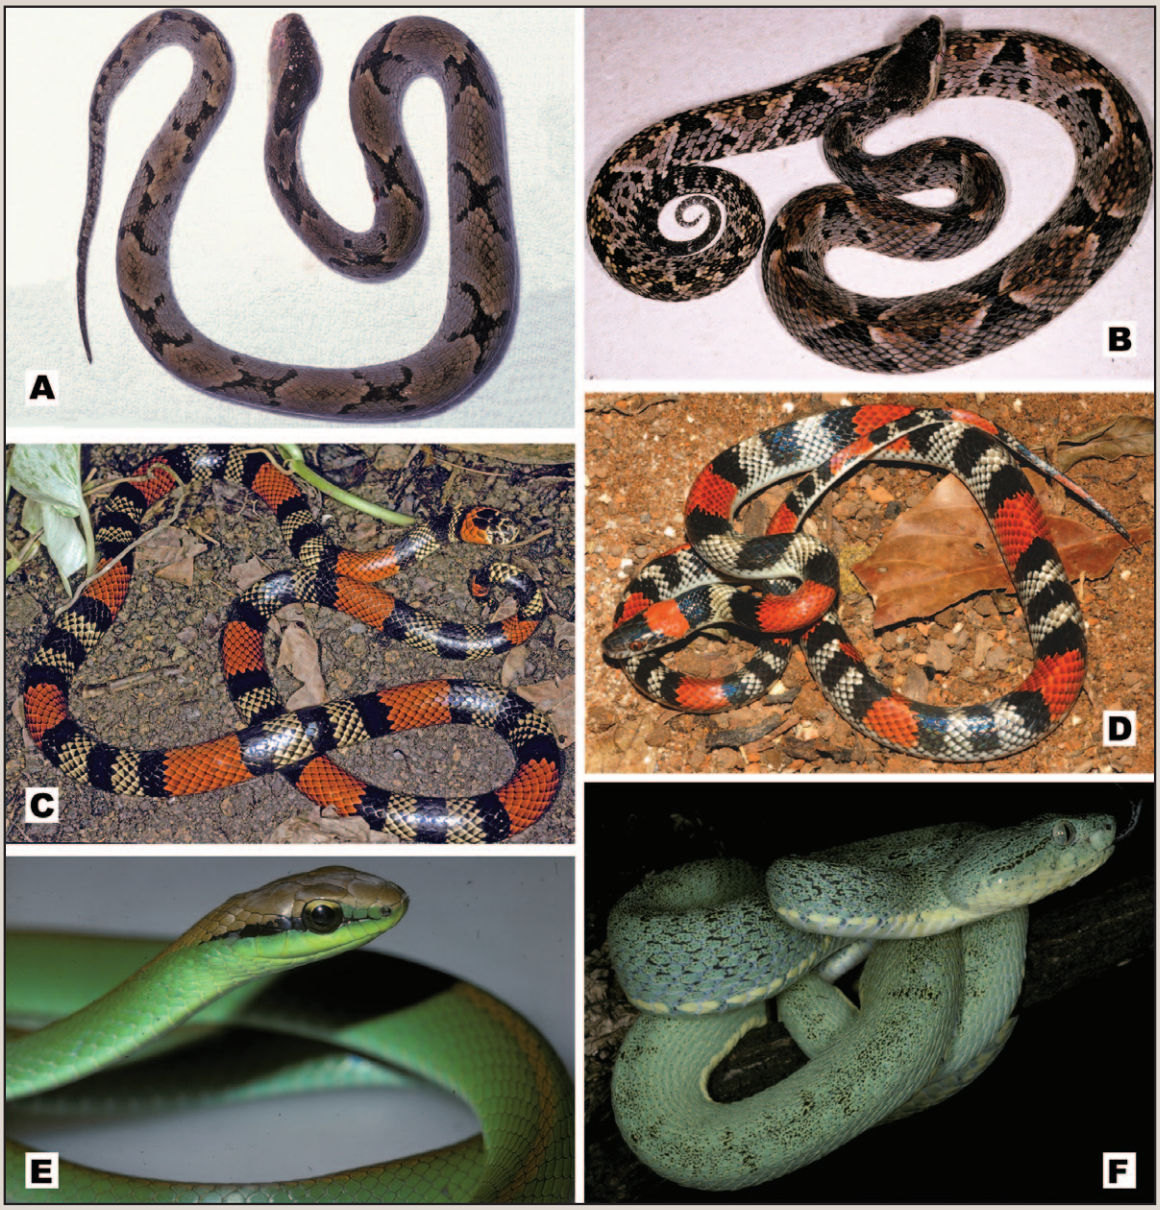
The Problems with Published NFFC Bite Cases and Accurate Risk Assessment

Several NFFC have repeatedly inflicted serious, life-threatening and/or fatal envenomings on humans (e.g., the natricines *R. tigrinus*, *R. subminiatus*, and the dispholidines *D. typus*, *Thelotornis kirtlandii*, *T. capensis*). However, the medical significance of the majority of NFFC taxa is unknown, and a recent comprehensive analysis of this question emphasized the paucity of well-documented medically significant bites, or "envenomings," inflicted by NFFC in the literature (Weinstein et al. 2011). Most of the published bite cases ascribed to NFFC lack sufficient documentation, rely on anecdotal information, and/or are authored/analyzed by non-medically qualified contributors. In many cases, auto-reporting by the victim him/herself introduces confusion because of the inclusion of purely subjective symptoms that are related to anxiety rather than envenoming. Certainly, there are also a number of common NFFC (e.g., Western Hognose Snake, *Heterodon nasicus*) that have inflicted bites that cause mild-moderate local effects, while the bites of other NFFC species (e.g., Lichtenstein's Racer, *Philodryas olfersii* and *M. monspessulanus*) rarely may cause systemic effects. Some previous authors have speculated about the possible medical importance of NFFC taxa that are popular in the commercial snake trade. As a result of these uncertainties, a number of taxa have acquired an unwarranted or premature reputation for inflicting dangerous bites. Many NFFC are popular in private collections, and since many species may have oral products/venoms worthy of biomedical investigation, it is important to establish standards for formally documenting any clinical case report describing their bites. These standards should be as rigorous as for any medical case study, whether it is for example complications of Dressler's syndrome or necrotizing epidermolysis associated with a new drug. These details should include formal identification of the specimen that inflicted the bite and clinical information, including results of thorough, repeated physical examination including formal testing for crucial signs and laboratory investigations. Unusual clinical signs should be documented photographically, a task facilitated by the widespread availability of mobile phone cameras. Anecdotal and circumstantial information must be identified as such and cannot be used to reach any conclusion about true medical risks, or the lack thereof, associated with the species of interest.

Speculation about the possible medical hazards posed by some NFFC has intermittently appeared in field guides, or regional herpetological accounts. Some of these include personal observations of mixed quality, while others include unverified descriptions of local effects of bites, as well as objectively unsupported reports of more serious systemic sequelae. For instance, Kudryavtsev and Mamet (1998) anecdotally described the mild local effects (mild pain, edema, lymphadenitis) of *Psammophis* spp. (sand snakes or racers) bites, and their description was concordant with other similar accounts (Weinstein et al. 2011). However, they also reported "extremely rare" progressive edema, nausea, "difficulties in breathing and moving," as well as ptosis (Kudryavtsev and Mamet 1998). Many casual readers often focus on the unverified and unqualified serious symptoms and signs and thus may uncritically perceive the species of interest as far more medically hazardous than the preponderance of evidence suggests. This also emphasizes the need for careful review of sufficient evidence regarding the hazard associated with any NFFC species prior to the assignment of relative medical risk. Also, medical hazard of any NFFC species cannot be accurately assessed solely on the presence of toxins in their oral secretions/venoms. However, this should not be interpreted to imply that bites from all NFFC without documented, clearly medically significant effects are without any possible medical concern, or that these snakes are necessarily "harmless." Aside from the species that are clearly capable of inflicting fatal bites, the bites of some taxa can cause systemic effects and/or significant local pathology that in some cases may resemble mild-moderate crotaline envenoming (Weinstein and Keyler 2009; Weinstein et al. 2011).

Several taxa of NFFC whose reputation for being particularly dangerous is based purely on anecdotal information (sometimes second- or third-hand) are outlined in Table 1. Bites by some of these species are alleged to have proved fatal to humans. We argue that this is not only inaccurate and misleading, but also poses possibly serious repercussions. Confused identification between some NFFC and medically important species of front-fanged snakes may occur due to their shared local vernacular names (e.g., cobra cipó [vine snake] or cobra verde [green snake] used in Brazil for several species of crotaline viperids, as well as for *P. olfersii*; see Fig. 1), as well as similar appearance of pattern (e.g., between *Xenodon severus* and *Bothrops brazili* and between several species of false coral snakes [e.g., *Erythrolamprus* spp., *Pliocercus* spp., and others] and coral snakes [*Micrurus* spp.]; see Fig. 1). Attention should also be given to common English names used for multiple species that may present confusion between NFFC species popular in the commercial trade and some species with significant medical hazard. For example, several species commonly called "vine snakes" include taxa that on occasion have inflicted bites with mild, and rarely, moderate local effects (e.g., *Oxybelis* spp.; *Ahaetulla* spp. [also known as whip snakes]), and others that have caused fatal envenoming (*Thelotornis* spp., also known as twig or bird snakes).

Several concerns emerge from these considerations:



- Some medical facilities located in regions where snake bite is a serious public health problem do not carefully distinguish the implications of local effects from bites by venomous vs. non-venomous snakes, and this can lead to inappropriate and dangerous unnecessary treatments (see Weinstein et al. 2011, for a review of some of these cases). For instance, patients presenting to some medical facilities in Brazil and South East Asia may be given antivenom for NFFC bites for which no specific antivenom exists and for which there is no clinical need. Thus, the patient is subjected to substantial risk (the possible adverse side effects of antivenom, including anaphylaxis which can be lethal, and serum sickness that can cause long-term disability) without any clinical basis or benefit. Thus, the accurate identification of hazard, whether termed "venom", or "toxic secretion" is of paramount importance to the bitten victim, and is not simply an academic exercise. The only effective antivenoms against venoms of NFFC are prepared against *D. typus* venom (South African Institute of Medical Research [SAIMR; now, South African Vaccine Producers, SAVP] boomslang antivenom, Johannesburg, South Africa) and that of *R. tigrinus* (anti-Yamakagashi antivenom, Japan Snake Institute, Gunma Prefecture, Japan) because these taxa have inflicted a number of well-documented fatal and life-threatening envenomings. Also, anti-*R. tigrinus* antivenom probably provides paraspecific

Table 1. Representative anecdotal cases of non-front-fanged colubroid snake (NFFC) bites suggesting fatal outcomes without supporting evidence.

Species, Family, Sub-family [1] [common names]	Features of cases	Nature of documentation	Remarks	Relevant references
Oligodon arnensis, Colubridae, Colubrinae [common, banded or russet kukri snake]	Third-hand account of sudden death of a young man attributed to a kukri snake sighted near the victim.	No established linkage between the presence of the snake and the death of the victim. There is no biomedical or clinical evidence that supports any hazard *Oligodon* spp.	An anecdotal case reported in a classical herpetological contribution. The medically qualified herpetologist author recorded his doubts about any linkage between the *Oligodon* and the reportedly fatal outcome.	Wall 1921; Weinstein et al. 2011
Philodryas olfersii, Colubridae, Dipsadinae[Lichtenstein's green racer; South American green racer; cobra cipó; cobra verde]	A purported "fatal" pediatric case often repeated in the literature.	Reported 4 years after alleged bite. Purely anecdotal, without any clinical documentation or supporting information.	Commonly cited as an excerpt, this rare "newsletter"-style publication of a little-known institution contains no supporting information about the alleged incident and is almost wholly a general public health warning of the dangers of snakebites in pediatric patients.	Centro de Informações Toxicológicas do Rio Grande do Sul 1996; Weinstein et al. 2011
Tachymenis peruviana, Colubridae, Dipsadinae [Peruvian slender snake]	There is no human bite recorded in the cited literature. The publication soley describes effects in experimental animals.	Contains no clinical information as the cited reference only involves effects of oral secretions on experimental animals.	Report contains no information about human bites.	Vellard 1955; Weinstein et al. 2011
Xenodon severus, Colubridae, Dipsadinae [mock viper; false fer-de-lance; yana yuta]	Third-hand anecdotal inference of fatal pediatric case.	There is no verified identity of the alleged snake involved in an unverified fatal case. The alleged snake is identified only by local jargon: "yana yuta."	Purely anecdotal report lacking any specific information or clinical detail. Identity of the snake is unknown and most parsimoniously is a misidentification of a crotaline viperid (see text Fig. 1).	Orcés 1948

[1]The taxonomy of NFFC is fluid and under active revision by several investigating teams. The taxonomy here follows that of Pyron et al. 2011.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. Some representative examples of confused identification between non-front-fanged colubroid (NFFC) and front-fanged snakes. Panels A and B demonstrate the similar appearance between a NFFC species, *Xenodon severus* (Panel A; mock viper or false fer-de-lance; yana yuta), and a pit viper, *Bothrops brazili* (Panel B; Brazil's Lancehead). Note the closely similar general dorsal patterns. Panels C and D also compare the appearance of a medically important elapid species, *Micrurus frontalis* (Panel C; Southern or Short-tailed Coralsnake; boipinima; coral venenosa), and that of a NFFC coral snake mimic, *Oxyrhopus trigeminus* (Panel D; False Coral Snake; boicora). The color and arrangement of bands are commonly confused. Panels E and F illustrate two medically important Brazilian snakes, Lichtenstein's Green Racer (*Philodryas olfersii*) and the green jararaca or Two-lined Tree Viper (*Bothriopsis* [*Bothrops bilineatus smaragdinus* sensu Monzel and Wüster 2008] *bilineata smaragdina*, Whithworth and Beirne 2011). The NFFC, *P. olfersii*, has recently been identified as a medically important species in Brazil. However, the vast majority of cases feature mild to moderate local effects, and only one well-documented systemic case involving widespread ecchymoses has been described. To date, there are no verified fatalities associated with bites from this species. However, envenoming by *B. bilineata* has resulted in occasional fatalities. These species can be called by the same vernacular names, e.g., cobra cipó, or cobra verde (and many others). Therefore, some species of NFFC and crotaline viperids may be confused in anecdotal accounts without voucher specimens because they are interchangeably named with the identical vernacular term. It is probable that some popularized anecdotal reports of fatalities attributed to some NFFC were based on bites inflicted by highly venomous viperids or elapids that were identified by using a regional name for the envenoming species that was shared among several non-venomous and venomous snakes.

protection against envenoming by *R. subminiatus*, although, to date, the handful of serious envenomings from this species have been managed without antivenom.
- Propagation in the literature of incorrect information about the medical risks of some NFFC requires correction. This is a difficult task as incorrect published material that is repeatedly cited can be hard to undo, particularly in the Internet age with its concomitantly wide distribution of/access to such information.
- Incorrectly associating fatalities (especially of children) with a given species of snake may lead to threats to natural populations of the species and excessive statutory regulation of the taxon.

There is a need for timely recognition of this problem as incorrect information regarding some of these snakes continues to be propagated in the toxinological and herpetological literature, as well as in Internet fora. As a current example, a recent paper incorrectly ascribed coagulopathy and "internal bleeding" to bites from *Philodryas olfersii* (Collaço et al. 2012). Analysis of the well-documented literature reveals only one verified case of systemic envenoming by *P. olfersii*, and that case featured only extensive ecchymoses distant from the bite site (Warrell 2004; Weinstein et al. 2011). There have been no well-documented cases of *P. olfersii* bites that have shown verified coagulopathy or "internal bleeding," although some authors (e.g., Collaço et al. 2012) may have misinterpreted ecchymoses as the clinical equivalent to "internal bleeding," a term that implies visceral hemorrhage. The extent of medical hazards associated with clinically significant *P. olfersii* bites remains unclear, and careful qualified contribution and analysis of additional cases may eventually illuminate this, but objectively unsupported anecdote should not be propagated in the literature. Also, Collaço et al. (2012) state that "...most cases of systemic envenoming have been treated with bothropic antivenom that neutralizes the toxic effects but has little effect on the local tissue damage." This is incorrect as the only information regarding "neutralization of toxic effects" of *P. olfersii* venom/Duvernoy's secretion by anti-bothropic antivenom/antibodies is primarily derived from *in vitro* studies (e.g., Assakura et al. 1992). Medically significant bites from *P. olfersii* and *P. patagoniensis* are among the few by NFFC that have received some formal study either through prospective, retrospective, or epidemiological review and critical analysis (de Madeiros et al. 2010; Ribeiro et al. 1999). None of these studies has supported the use of anti-bothropic antivenom for treatment of *P. olfersii* bites, the vast majority of which are limited to mild-moderate local effects, and the rare more serious sequelae require greater documentation in order to characterize the possible clinical outcomes from the more significant bites by this species. As stated previously, the notably unfavorable risk: benefit profile of using antivenom of unproven efficacy for any bites inflicted by this species cannot be clinically justified.

Conclusions

In conclusion, whenever possible, several essential features must be part of formal reports describing medically significant bites by NFFC:
- A physician must have reviewed anyone receiving a medically significant bite from a NFFC, and the salient results of the physical examination, investigations, etc., included in the report.
- Whenever possible, the NFFC responsible for the bite should be formally identified by an academic herpetologist or qualified clinical toxinologist, and, ideally, the specimen should be photographed and provided to a museum collection with an assigned accession number.
- Investigators must be wary of regionally used common names applied to unavailable specimens involved in any medically significant snake bite, as these may be used for snakes of similar appearance, whether they be NFFC, or medically important crotaline viperids or elapids.
- A clinically detailed case report should be carefully prepared and submitted to an appropriately refereed journal. The referees should primarily be physicians, ideally with herpetological and/or toxinological training. The victim should not be the senior author, even if he/she is medically qualified. Even though cases describing minimal medical effects are likely to be difficult to publish, as editors of clinical journals may not comprehend their importance, an effort to formally document them should be made. Such cases are important as they help establish/build an accurate risk profile for otherwise undocumented/unverified NFFC. Thus, the documented absence of medically significant effects can be as important as the recording of their presence.
- Anecdote and/or unverifiable information should be avoided, and must not be included in the case report without clear qualification.
- Obscure literature describing an unusual or particularly serious effect of a bite from any NFFC must be checked first-hand, and never cited without careful review (and qualified translation if necessary) of the original publication.
- Field guides describing and illustrating NFFC species that either have an established medically significant risk profile or lack well-documented clinical information describing/analysing their bites, should recommend caution and strongly discourage careless handling of these snakes. It must be emphasized that unverified or unestablished medical risk does not imply a lack of hazard (unverified ≠ harmless!). A physician should promptly review those receiving a NFFC bite that produces significant local effects or distressing signs/symptoms.

Acknowledgments.—We thank David J. Bates for his helpful comments, and Anna Bjersby of the Stockholm University library for her valuable assistance in locating several rare references.

Population Genetic Structure and Revised Geographic Range for the Tridactyl Skink (*Brachymeles muntingkamay*) from Luzon Island, Philippines

The genus *Brachymeles* represents a unique radiation of semi-fossorial (burrowing) lizards, all but two of which are endemic to the Philippines in Southeast Asia (Siler et al. 2011a, 2012b). Although all species can be described as slender, brown, and small- to medium-sized, this radiation represents one of the best systems for studying the evolution of limb reduction and loss; body forms within the genus range from pentadactyl to externally limbless (Siler and Brown 2011). Over the last decade, a renewed effort at understanding evolutionary patterns within *Brachymeles* has resulted in the discovery of 21 new species previously unknown to science or masquerading within the range of a previously recognized, widespread, and morphologically diverse species (Siler 2010; Siler and Brown 2010, 2011; Siler et al. 2009, 2010a,b, 2011a,b,c,d, 2012a,b). Although the dense survey efforts leading to these discoveries have filled in many gaps in our understanding of this radiation, there still remain species with unique body plans that are poorly represented in collections and are far less understood (Siler 2010; Siler et al. 2011c,d, 2012a).

Many of the species representing unique digit classes within the genus are micro-endemics, with recognized ranges currently limited to single sites. Among these taxa, several low-elevation species have persisted despite nearly complete deforestation across their limited ranges on Mindanao and Cebu islands (*B. cebuensis*, *B. pathfinderi*); until rediscovered in 2009, *B. pathfinderi* had not been observed for more than 80 years (Siler et al. 2011c). Other taxa include several mid-to-high elevation species (*B. elerae*, *B. muntingkamay*, *B. wrighti*), with *B. elerae* and *B. wrighti* long represented in museum collections by only a few specimens (Siler et al. 2011d). All three of these species occur in the mountainous terrain of northern Luzon Island in the Philippines. Interestingly, all micro-endemic taxa are non-pentadactyl, with finger counts ranging from 3–5 and toe counts ranging from 2–4.

Brachymeles muntingkamay Siler, Rico, Duya, and Brown, 2009 is one of 36 recognized lizard species of *Brachymeles*, and is one of only four species known to possess three digits on the fore- and hind limbs. This unique species was discovered only recently in mid- to high-elevation forest on Mt. Palali in the northern portions of Luzon Island, and has since been presumed to be endemic to this single, isolated mountain peak in the Caraballo Mountain Range of central Luzon. During a recent survey around the caldera of Mt. Cagua in the extreme northeastern portion of Luzon Island, a second montane population of this species was discovered.

From 7–23 July 2011, seven adults and one juvenile of *Brachymeles muntingkamay* were collected during herpetological field surveys in mid- to high-elevation forest on Mt. Cagua, in extreme northeast Luzon Island, Philippines (Fig. 1). Here we report on this newly discovered population of *B. muntingkamay* from Mt. Cagua, located in the northern extreme of the Sierra Madre Mountain Range. The new population is not only geographically disjunct from the type locality of *B. muntingkamay*, but is located in a completely disparate mountain range on the island. With this new discovery, we present data on the genetic identity and structure between the two geographically disjunct populations, provide new photographic and morphological data for the species, revise the known geographic range of *B. muntingkamay*, and discuss the implications of this discovery for future research involving other unique (and possibly rare) mid- to high-elevation vertebrate species in the Philippines.

Materials and Methods.—Field survey protocols follow Brown et al. (1996, 2000), Diesmos et al. (2005), Siler et al. (2011e), and McLeod et al. (2011). Vouchered specimens collected in the field were deposited in the University of Kansas Natural History Museum (KU) herpetological collections and the National Museum of the Philippines (PNM). We examined fluid-preserved specimens for variation in qualitative and mensural characters. Sex was determined by gonadal inspection, and measurements were taken to the nearest 0.1 mm with digital calipers by CDS. X-rays were taken with a company cabinet X-ray on Kodak MIN-R 2000 film exposed at 5 milliamperes and 30 volts for 1 minute 15 seconds. Meristic and mensural characters were chosen based on Siler et al. (2009): snout–vent length, total length, tail length, paravertebral scale-row count, supralabial count, infralabial count, supraciliary count, and supraocular count. Additionally, we counted the number of presacral vertebrae from x-ray images of specimens. A summary of representative diagnostic characters highlighting the minor variation observed between mountain populations is provided in Table 1.

Genetic samples of *B. muntingkamay* from the recently surveyed site in the Municipality of Gonzaga were used to investigate the northeastern population's identity, as well as its genetic similarity with the type populations of topotypic *B. muntingkamay* from Mt. Palali, central Luzon (Fig. 1). The dataset included newly collected sequences of the mitochondrial gene NADH dehydrogenase subunit 2 (*ND2*), supplemented by published *ND2* sequence data from *B. elerae* and *B. boulengeri* for use as outgroup samples (Siler et al. 2011a). We follow the methods described in Siler et al. (2012c) for calculating haplotype networks. All Mt. Cagua specimens were initially identified on the basis of body and head scalation patterns (Siler et al. 2009).

The newly collected *B. muntingkamay* specimens include: KU 330086, 330087, 330089–93, seven adult females; KU 330088,

juvenile. All specimens were collected on Mt. Cagua, Barangay Magrafil, Municipality of Gonzaga, Cagayan Province, Luzon Island, Philippines (18.22538°N, 122.11445°E; 694 m elev.; WGS 84; Fig. 1). Voucher information corresponding to data from novel sequences deposited in GenBank, and haplotype labels corresponding to those shown in Figure 1, are included in Table 2.

Results and Discussion.—The haplotype network reveals some degree of haplotype diversity within and between the two sampled populations of *Brachymeles muntingkamay* (Fig. 1). Both populations are recovered as genetically distinct, albeit with low genetic divergence observed between the two allopatric populations (uncorrected pairwise sequence divergence 1.2–1.4%; Fig. 1). Intraspecific genetic structure within both sampled populations appears similar based on the few individuals sampled for this study.

Meristic and mensural characters of the newly discovered population are consistent with the recognized diagnostic characters for *Brachymeles muntingkamay* (Table 1). Character variation observed between the Mt. Palali and Mt. Cagua populations includes (Table 1): 1) presacral vertebrae 42 at Mt. Cagua (versus 42 or 44 at Mt. Palali); 2) supraciliaries 6 at Mt. Cagua (versus 6 or 7 at Mt. Palali); 3) supraoculars 5 at Mt. Cagua (versus 5 or 6 at Mt. Palali); and 4) prefrontals separated at Mt. Cagua (versus in medial contact at Mt. Palali). All other diagnostic characters for *B. muntingkamay* (Siler et al. 2009) were observed to be consistent (CDS, pers. obs.).

TABLE 1. Summary of representative meristic and mensural characters among adult specimens from the two disjunct populations of *Brachymeles muntingkamay*. Sample size, body length, and tail length are included for reference (snout–vent length, total length given as range over mean ± standard deviation).

	Mt. Palali	Mt. Cagua
Sample size	12 female	7 female
Number of digits (fore/hind)	3/3	3/3
Snout–vent length	61.8–81.3	61.8–81.3
	(73.6 ± 5.9)	(73.6 ± 5.9)
Total length	107.4–136.0	109.7–116.4
	(124.0 ± 8.6)	(113.3 ± 2.9)
Tail length/snout–vent length	50–79	53–85
	(65 ± 10)	(64 ± 14)
Presacral vertebrae number	42, 44	42
Paravertebral scale-row count	85–90	87–88
Supralabial count	6 (12)	6 (7)
Infralabial count	6 (12)	6 (7)
Supraciliary count	6 (10)	6 (7)
	7 (2)	
Supraocular count	5 (11)	5 (7)
	6 (1)	
Prefrontal contact	Present	Absent

TABLE 2. Summary of specimens corresponding to genetic samples included in the study. Haplotype identification numbers (ID) correspond to those shown in Figure 1. KU = University of Kansas Natural History Museum.

KU 308953	Mt. Palali, Barangay Maddiangat, Municipality of Quezon, Nueva Vizcaya Province, Luzon Island, Philippines	1	JX966370

Brachymeles muntingkamay is now recognized to occur in separate and distinct geological units of Luzon Island: the Caraballo and the Sierra Madres mountain ranges (Fig. 1). The species occurs in primary- and secondary-growth forest at mid-elevations (Siler et al. 2009). All newly collected individuals from Mt. Cagua were observed within small, rotting logs. Interestingly, all individuals of *B. muntingkamay* observed at both localities are females. Given what is known now about species in the genus, we suspect that the absence of male specimens is simply a result of sampling effort, and future surveys conducted in these regions of Luzon Island will likely result in the observation of male individuals. Whether males of this species possess a unique behavior relative to females that has led to gender bias in collections remains unknown, and in-depth studies are needed on the natural history of this unique mid-elevation species. *Brachymeles muntingkamay* remains one of only three limbed, non-pentadactyl species that occur at higher elevations (incl. *B. elerae* and *B. wrighti*; Siler 2010; Siler et al. 2011d). The discovery of a high elevation, isolated population of *Brachymeles muntingkamay* more than 200 km from the type locality brings to light questions regarding the full distribution of this species.

While a few biotic surveys have been conducted within the intervening landscape (Brown et al. 2000, 2012, 2013; Siler et al. 2011e), the presence of this species in intervening areas between Mt. Cagua and Mt. Palali has yet to be documented. Due to the limited access to suitable, mid- to high-elevation habitat, it is likely that additional populations may be present along central and southern portions of the Sierra Madre Mountain Range. However, this can only be validated with continued survey efforts, targeting higher elevation habitat in intervening areas (e.g., Cagayan and Isabela Provinces). Until such time, the distribution of this species is known only from two disjunct, mid-elevation localities. With this new data, we have re-evaluated this species against the IUCN criteria for classification, and find that it does not qualify for Critically Endangered, Endangered, Vulnerable, or Near Threatened status. *Brachymeles muntingkamay* is quite abundant on both Mt. Palali and Mt. Cagua, and we predict the species has a broad geographic distribution throughout the Sierra Madres Mountain Range at mid- to high elevations. We therefore classify this species as Least Concern LC (IUCN, 2011).

This discovery has major implications for conservation biology of reptiles in the mountains of the northern Philippines, with the possibility of underestimated ranges for mid- and high-elevation micro-endemic species, especially on topographically complex islands like Luzon and Mindanao. Just considering ground skinks, the newly discovered montane population of *B.*

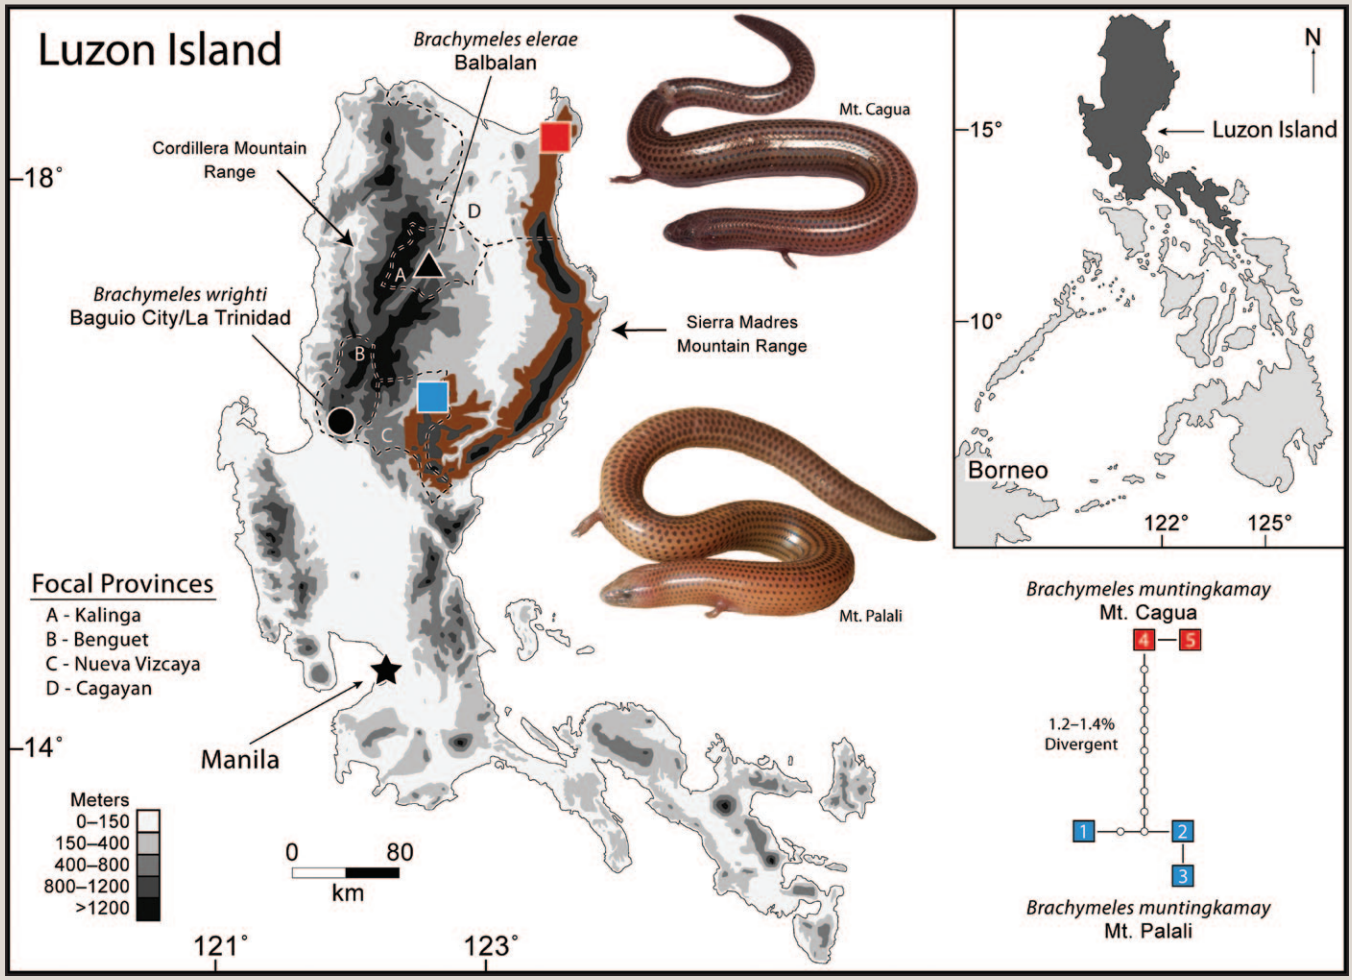

FIG. 1. Known localities of *Brachymeles muntingkamay*, with provincial boundaries for known populations of the three mid- to high-elevation species of *Brachymeles* on Luzon Island, Philippines. Hypothesized distribution of *B. muntingkamay* highlighted in brown. The minimum spanning, 95% connection probability, statistical parsimony haplotype network is shown depicting population-level genetic structure between and within the two sampled populations. Haplotype numeric labels and colors correspond to sampled individuals and localities (refer to Table 2). Photographs in life of *B. muntingkamay* from Mt. Cagua and Mt. Palali shown for comparison.

muntingkamay provides hope for future discoveries of the only two tetradactyl species in the genus *Brachymeles* (*B. elerae* and *B. wrighti*), as well as the poorly known Cordillera endemic species of *Eutropis* (*E. bontocensis*). At present there remain only two known specimens of *B. wrighti*, five specimens of *B. elerae*, and three specimens of *E. bontocensis* in museum collections. Unfortunately, both *B. wrighti* and *E. bontocensis* have not been observed in over 80 years, and our three focused surveys of the type localities for *B. wrighti* have resulted in no new records. Although such sparse data on the distribution of these species prevents a complete assessment of their geographic distribution, renewed survey efforts throughout the Cordillera Mountain Range may result in the discovery of additional populations of these vulnerable species. Fortunately, recent studies have indicated that many species of *Brachymeles* appear to be resilient to habitat degradation (Siler 2010; Siler and Brown 2010; Siler et al. 2011b,c,d, 2012a,b), and we remain optimistic that future surveys will result in similar discoveries of montane poopulations.

Acknowledgments.—We thank the Protected Areas and Wildlife Bureau (PAWB) of the Philippine Department of Environment and Natural Resources (DENR) for facilitating permits necessary for this and related studies and we are particularly grateful to M. Lim, C. J. L. De Leon, Custodio, and A. Tagtag for their logistical support of our research. The University of Kansas IACUC Facility approved all animal care and handling protocols. The Mt. Cagua Protected Area Management Board graciously endorsed our application to conduct field research in the Gonzaga area, Calayan Province. For assistance and companionship in the field, we thank J. Fernandez, P. Buenavente, V. Yngente, W. and J. Bulalacao, and C. Oliveros. We thank two anonymous reviewers for comments on an earlier draft of this manuscript. This work was supported by a U.S. National Science Foundation Biotic Surveys and Inventories grant (DEB 0743491).

The Dog-faced Water Snake (*Cerberus rynchops*) and Gerard's Mud Snake (*Gerarda prevostiana*) at the Western Edge of Their Distribution

The homalopsid snake genus *Cerberus* has been recently revised (Murphy et al. 2012), and now contains five species that range from India's northwest coast (at 22°N) to Australia's Gulf of Carpentaria (at 18°S), a straight-line distance of over 8000 km (~ 20% of the Earth's circumference). *Cerberus* has a coastal distribution, and is mostly restricted to the intertidal zone characterized by mud flats, tidal creeks, mangrove forests, and Nipa Palm (*Nypa fruticans*). Thus, its geographic distribution has a strong linear component; when the distance is measured following the major coastlines of India, Bangladesh, Myanmar, the Malay Peninsula, the Sunda Shelf, the Lesser Sunda Islands and the Sahul Shelf, its linear range exceeds 11,000 km (Murphy et al. 2012). The monotypic *Gerarda prevostiana* has a coastal distribution somewhat similar to the genus *Cerberus*, one that extends from India's west coast to the Philippines (Murphy 2007). *Gerarda*, however, is not as well known as *Cerberus*. Its smaller size and secretive behavior within the intertidal burrow system has resulted in few museum specimens and fewer observations on its natural history, although it was first reported from western India by Wall (1921).

Cerberus rynchops has a South Asian distribution. On the eastern edge of its range, it extends to the Mouth of the Irrawaddy, Myanmar and perhaps into the Mergui Archipelago, where it is replaced by *Cerberus schneiderii* along the Andaman Sea coast of Thailand and coastal Southeast Asia (Murphy et al. 2012). The western edge of the distribution of *C. rynchops* was reported to be in the vicinity of Mumbai, India (Murphy 2007; Murphy et al. 2012; Smith 1943; Whitaker 1969), but Vyas (1996) and Gadhvi and Vyas (2002) had noted its presence about 170 km north of Mumbai, in the rivers and estuaries of Gujarat, India. Here, we provide specific localities, document the identity of the snake with photographs, and discuss the habitat and abundance of *Cerberus* and *Gerarda* at the western edge of their respective ranges.

Cerberus and *Gerarda* (Fig. 1) were found at eight localities in the Gulf of Khambaht in Gujarat where notes on habitat and relative abundance were taken (Table 1). The surveys of 5–7 h were conducted by 2–3 observers during daytime hours and at low tide. The Tapti River estuary near Hazira town and the Auranga River estuary adjacent to the Valsad coastal area were surveyed 3–5 times while the other locations were surveyed only once. The habitat observations support the association of *C. rynchops* with mangroves and tidal flats of mud and sand (Table 1 and Fig. 2 A–E) and of *Gerarda prevostiana* with mangroves. Abundance estimates for *Cerberus* at these locations fall into two broad categories. Snakes were considered rare when only a single specimen was observed on a survey and in good numbers when several individuals were observed on each visit.

On the south side of the Gulf of Kutch (Fig. 2), numerous coastal areas were surveyed from Dwarka and Okha at the mouth of the Gulf of Kutch to Jamnagar inside the gulf. In addition, coastal areas near Mandvi and Mundra on the north side of the Gulf of Kutch were surveyed at least once. The coastal areas in the Gulf of Kutch include tidal flats of mud and sand, numerous tidal creeks, and mangroves in varying densities. No *Cerberus* or *Gerarda* were observed at any of the Gulf of Kutch survey sites.

The survey data suggest the 53,200 ha intertidal wetlands of the Gulf of Khambhat (Sevlan 2003) is the western edge of distribution for both *Cerberus* and *Gerarda*. Neither is known from the Gulf of Kutch, a 58,200 ha wetland (Selvan 2003), about 270 km to the northwest of the Gulf of Khambhat. Both of these Gujarat wetlands are somewhat unique in that most of their freshwater supply does not come from a major river, but from rainfall and smaller streams. While the Gulf of Khambhat receives about 900 mm of precipitation annually, the Gulf of Kutch receives only 470 mm of precipitation annually, and both are classified as drowned

FIG. 2. A map providing survey locations (details in Table 1) in Gujarat, India. A–E show *Cerberus rynchops* and *Gerarda prevostiana* habitats in the Gulf of Khambaht. A) Low tide near Ghogha village, 10 Feb. 2005; B) Fishing net near Ghogha village during low tide, 10 Feb. 2005; C) Low tide near the mouth of the Tapti River at Hazira town, 19 Feb. 2008; D) Mouth of tidal creek at low tide in the Narmada River estuary, 30 Dec. 2010; E) Shentrunji River, near Sartanpar village.

TABLE 1. The localities surveyed in the Gulf of Khambaht, Gujarat, India. Summary information on the coordinates, intertidal habitat, and snake abundance are provided.

Locality	Coordinates	Intertidal Habitat	Abundance
Jafrabad sea coast, Amreli District	20°51'23.54"N; 71°22'21.47"E	Mixed sand and mud shoreline with sparse mangroves	*Cerberus* reported by local snake rescuer (Dinesh Goswami); *Gerarda* not observed.
Sartanpar village, nr. Town of, Talaja, Bhavanagar District	21°17'12.69"N; 72°6'0.51"E	Packed mud with sparse mangroves on south bank of Shentrunji River	*Cerberus* and *Gerarda* are rare in the Shentrunji River estuary.
Kuda village, Bhavanagar District	21°36'41.08"N; 72°17'30.74"E	Firm sand shoreline with no mangroves	*Cerberus* and *Gerarda* are rare along the sea shore.
Ghogha village, Bhavanagar District	21°40'5.61"N; 72°16'44.00"E	Soft mud with dense mangroves; see Fig. 2A, B	*Cerberus* and *Gerarda* rare along shoreline.
Mahi River mouth, Anand, Bharuch, and Valdodara Districts	22°15'58.00"N; 72°52'21.00"E	Soft mud with sparse mangroves	Both *Cerberus* and *Gerarda* are rare in the area.
Narmada River estuary, Bharuch District	21°39'18.00"N; 72°49'34.00"E	Soft mud with mangroves	Intermediate numbers of *Cerberus* and *Gerarda*, fewer than Tapti River estuary.
Hazira town, Surat District	21°5'57.49"N; 72°41'48.18"E	Tidal creeks with soft mud and good numbers of mangroves; see Fig. 2C	Good numbers of *Cerberus* found in the Tapti River estuary, *Gerarda* present but not common.
Valsad coastal area, nr.Valsad town, Valsad District	20°36'31.65"N; 72°53'30.32"E	Muddy shoreline with sparse mangroves	Good numbers of *Cerberus* and *Gerarda* were found in the Auranga River estuary.

valley type mangroves. The Gulf of Khambhat has a dry season lasting eight months; the Gulf of Kutch has a dry season nine months or slightly longer. The climate for both gulfs is hot with a rather cold winter, maximum - minimum temperatures 40°C (May–June) and 10°C (January–February) and combined with the extended dry season the mangroves in this region are considered to be arid zone communities. Additionally, the low volume of freshwater entering both of these estuaries results in high salinity at both locations (Rashid 1985; Selvan 2003).

Murray (1884, 1886) reported *Cerberus rynchops* from Karachi and the Sindh Coast (the Indus River Delta) of Pakistan, about 600 km northwest of the Gulf of Khambhat, but Minton (1966) and Khan (2002) could not document its presence in this region. The environmental conditions in the Indus Delta may prevent *Cerberus* from permanently colonizing the area. Barkati and Rahman (2005) describe the habitat as the most arid land mangroves in the world, with the area receiving only 221 mm of precipitation per annum. In addition, they report water temperatures ranging from 20 to 33°C, and averaging 26.1, 27.3, and 25.2°C at three different locations in the Indus Delta. These average temperatures are below the 30°C body temperatures reported for other homalopsid snakes (Murphy et al. 1999). Yet, it should be noted that there is a homalopsid endemic to the Indus delta, *Enhydris pakistanica*, a poorly known, highly aquatic species that represents the most western population of the family Homalopsidae.

Sea surface temperatures are warm enough for *Cerberus* from Khambaht to the Indus most of the year. However, January (and maybe February) temperatures may be too low and therefore thermally stressful for both species north of the Gulf of Khambaht. Seasonally low levels of surface freshwater (rain and runoff) and high salinities may also be an important factor throughout the region but particularly north of the Gulf of Khambaht. Mangrove habitats and mud flats do not seem to be limiting in this region and are present from the Gulf of Khambaht to the Indus. Pockets of *Cerberus* and/or *Gerarda* may have occurred in the past or may now occur northwest of the Gulf of Khambaht but physical factors may cause frequent local extinctions, similar to the salinity crisis observed in Lake Songkhla, Thailand in 1999 (Murphy 2007).

Early in the 18th century, one of the Indus canals and the Indian Banas and Saraswati rivers carried substantial freshwater flows in Rann of Katch. This might have reduced the salinity and created optimum habitat for the species. A high magnitude (7.9 Richter scale) earthquake on 16 June 1819 uplifted an area 80 km long, 6 km wide, and 6 m high, known as Allah bund in the Greater Rann of Kutch. This event altered the course of Narra River (eastern branch of Indus). By the mid-19th century, all these rivers had reduced flow due to construction of dams for irrigation purposes (Mukhtar and Hannan 2012; Thakkar et al. 2012). The Indus mangroves are now extremely degraded as the result of the scarcity of freshwater, siltation, industrial pollution, deforestation for fire wood, and rapid urbanization and Mukhtar and Hannan (2012) predict the disappearance of the forest in the next two decades.

Although Murray's (1884) record of *Cerberus* may have been a misidentified *Xenochrophis* (Minton 1966), it is also possible that *Cerberus rynchops* had an established population in the Indus delta in the 19th century and a combination of anthropogenic habitat modification, seismic alterations, and marginal thermal conditions combined to produce a sub-optimal habitat resulting in the extirpation of the population.

Morphological and Molecular Variation in the Endemic and Poorly Known Honduran Jumping Pitviper *Atropoides indomitus* (Serpentes: Viperidae), with Notes on Distribution

Smith and Ferrari-Castro (2008) described *Atropoides indomitus* based on one adult male (UTA R-52952) and one adult female (USNM 337487) from two localities in southwestern Colón and northwestern Olancho, Honduras (Fig. 1). Castoe et al. (2005) had previously identified the distinctness of this species based on mitochondrial DNA sequence data that placed it as sister to the Guatemalan *A. occiduus* (Hoge). McCranie (2011) presented morphological data from two additional females (USNM 578404–05) of this taxon from north-central Olancho in the vicinity of the species' type locality. Furthermore, a juvenile *Atropoides* sp. (UNAH 4425) was subsequently examined from a locality in south-central El Paraíso, Honduras, that appeared morphologically similar to *A. indomitus* (McCranie 2011). However, due to the large distance from any known *Atropoides* localities, McCranie (2011) remarked that additional specimens, including tissue samples, were needed from the El Paraíso locality before that population could be assigned to a described species.

Subsequently, four additional specimens (MVZ 267165–67, UNAH 5651) from the El Paraíso locality have become available, including two tissue samples. Thus, the goals of this study are threefold. First, we identify the *Atropoides* specimens from the El Paraíso locality using mitochondrial sequence data. Second, we describe the morphological variation of these four additional specimens. And third, we compare the four additional specimens to *A. indomitus* from the type and paratype localities and to its sister species *A. occiduus* using morphological and molecular data.

Methods

Molecular data.—Muscle tissue was obtained from two of the four *Atropoides indomitus* (MVZ 267165 and UNAH 5651) specimens collected from near Mapachín, El Paraíso, Honduras, and stored in 95% ethanol. Genomic DNA was isolated from tissues using a Qiagen DNeasy kit (Qiagen, Valencia, California, USA). For these samples, we amplified a 661 base pair region of the mitochondrial NADH dehydrogenase subunit 4 (ND4) without using tRNAs with the primer set (Arévalo et al., 1994) of forward primer ND4 (5'-CACCTATGACTACCAAAAGCTCATGTAGAAGC-3') and reverse primer LEU (5'-CATTACTTTTACTTGGATTTGCACCA-3'). All amplification reactions used GoTaq® Green Master Mix, 2X (Promega Corporation, Madison, Wisconsin, USA). Thermal cycling was performed on a GeneAmp® PCR System 9700 machine (Applied BioSciences, Foster City, California, USA). The ND4 fragment was amplified using an initial 5 min denaturation cycle at 95°C, followed by 30s denaturing at 94°C, 45s annealing at 52°C and 1 min extension at 72°C for 38 cycles, and a final 5 min extension at 72°C. PCR product was quantified by visualization on 1% agarose gel stained with ethidium bromide. Successfully amplified PCR products were prepared for sequencing by using the ExoSAP-IT kit (United States Biochemical). A BigDye Terminator Cycle Sequencing Kit (Applied Biosystems Inc.) was used for sequencing following the manufacturer's protocol and using PCR primers. The sequenced products were precipitated using an ethanol/sodium acetate method and rehydrated in HPLC purified formamide (HIDI). The sample was then analyzed on an ABI PRISM 3100xl Genetic Analyzer in the Genomics Core Facility at the University of Texas at Arlington, USA.

Alignments were constructed and edited by eye using the program Sequencher 4.8 (GeneCodes, Ann Arbor, Michigan, USA) and genetic distances (uncorrected "p") were generated in PAUP* (Swofford 2002). Resulting DNA sequences from this analysis were submitted to GenBank (accession numbers: KC354700 and KC354701).

Morphological data.—Specimens were initially fixed in 10% formalin and transferred to 70% ethanol two to four months later. Length data were taken to the nearest 1.0 mm using a ruler. We used the same terminology for scales and method of counting ventral scales as described by Smith and Ferrari-Castro (2008). The color codes and names follow those of Smithe (1975–1981).

Results

Molecular variation.—The two *Atropoides* specimens from El Paraíso (MVZ 267165 and UNAH 5651) shared identical ND4 haplotypes (i.e., 100% DNA sequence similarity). These two specimens had an ND4 haplotype only slightly divergent (0.30%) from the Honduran *A. indomitus* (as *A. occiduus*; UTA R-52952) specimen identified by Castoe et al. (2005). However, the three Guatemalan *A. occiduus* specimens identified as sister taxa to *A. indomitus* (UTA R-24763, 29680, 46719; Castoe et al., 2005) each had ND4 sequences about 6.0% (6.4, 5.9, and 5.8%) divergent from MVZ 267165, UNAH 5651, and UTA R-52952. Divergence among the three Guatemalan *A. occiduus* sequences was less than 1.0% (0.45, 0.46, and 0.91%). Given the sequence similarity between MVZ 267165, UNAH 5651, and UTA R-52952, we identify MVZ 267165 and UNAH 5651 as *A. indomitus*.

Morphological variation.—Smith and Ferrari-Castro (2008) distinguished *Atropoides indomitus* from *A. mexicanus* (Duméril, Bibron, and Duméril), the only other species of *Atropoides* known to occur in Honduras, based on number of ventrals (140 in both the single male and single female *A. indomitus* versus maximum of 130 in male and 135 in female *A. mexicanus*),

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

number of scales between the prelacunal and second supralabial (1 in *A. indomitus* versus 2–3 in *A. mexicanus*), number of nasorostrals (0–1 in *A. indomitus* versus 2–4 in *mexicanus*), rostral apex condition (reaching canthal ridge in *A. indomitus* versus not reaching canthal ridge in *A. mexicanus*), postorbital stripe condition (including temporal rows 2 and 3 at midlength in *A. indomitus* versus rows 3 and 4 in *A. mexicanus*), and in subocular spot condition (large and distinct in *A. indomitus* versus usually absent, small when present, in *A. mexicanus*). In addition, *A. indomitus* was thought to be a smaller species than *A. mexicanus* (maximum known total length [TOL] 573 mm in *A. indomitus* versus 938 mm in *mexicanus*). Morphological data from two *A. indomitus* subsequently collected from the vicinity of the type locality (McCranie 2011) supported the diagnostic characters given for the species by Smith and Ferrari-Castro (2008).

Smith and Ferrari-Castro (2008) distinguished *Atropoides indomitus* from *A. occiduus* in part based on number of ventrals (140 in both the single male and single female *A. indomitus* versus maximum of 135 in male and 137 in female *A. occiduus*), subocular spot condition (not contacting orbit in *A. indomitus* versus contacting orbit in *A. occiduus*), condition of dark spot below pit (small and only encompassing prelacunal and adjacent edges of postlacunal and foveals in *A. indomitus* versus large and encompassing prelacunal and most of postlacunal and foveals in *A. occiduus*), and ventral pattern (nearly immaculate in *A. indomitus* versus dark ventrolateral blotches or heavy mottling in *A. occiduus*). Morphological variation in all five El Paraíso

specimens (MVZ 267165–67, UNAH 4425, 5651) agree with that of the Colón and Olancho *A. indomitus* specimens as described by Smith and Ferrari-Castro (2008) and McCranie (2011; see Table 1).

Color in life of an adult female (MVZ 267165) from the El Paraíso population was recorded as follows: dorsal ground color Russet (34) with Vandyke Brown (121) dorsal and lateral blotches; top of head Russet with Vandyke Brown postocular stripe; side of head below postocular stripe yellowish brown with Russet subocular spot; ventral surface of head cream medially, yellowish brown laterally; venter of body yellowish brown with slight dark brown flecking anteriorly, grading to heavily flecked and mottled with dark brown posteriorly; subcaudal surface Vandyke Brown with yellowish brown mottling on anterior two-thirds, pale brown on posterior third. The pale ventral surfaces in life of MVZ 267165, along with the pale ventral surfaces, the distinct subocular spot not reaching the orbit, the postorbital stripe involving temporal rows 2 and 3 at midlength, and the tiny spot below the pit in all El Paraíso specimens in alcohol agree with *A. indomitus* and not *A. mexicanus* or *A. occiduus*. Figure 2 shows a specimen of *A. indomitus* from El Paraíso in life.

The hemipenis from an El Paraíso specimen (UTA R-59770; extracted from UNAH 5651) agrees in most aspects with the *Atropoides indomitus* hemipenis described and illustrated by Smith and Ferrari-Castro (2008) and Jadin et al. (2010), except the small spines between the levels of bilobation of the organ and bifurcation of the sulcus spermaticus are slightly larger in the El Paraíso specimen than in the *A. indomitus* holotype.

Discussion

The results of this study are consistent with those of previous studies that suggest *Atropoides indomitus* to be a distinct species and sister to *A. occiduus* (Castoe et al. 2005, 2009; Daza et al. 2010; Smith and Ferrari-Castro 2008). Studies estimating divergence times among *Atropoides* species suggest that *A. indomitus* split from *A. occiduus* during the Pliocene (Castoe et al. 2009 [as *Atropoides* sp.]; Daza et al. 2010).

The diagnostic scale and size data for the five *Atropoides indomitus* specimens from El Paraíso are listed in Table 1. These diagnostic data, the color patterns, and the hemipenial morphology all agree with those of the *Atropoides indomitus* from Colón and Olancho as given by Smith and Ferrari-Castro (2008) and McCranie (2011) and along with the new molecular data reported herein, further support recognition of the El Paraíso population as *A. indomitus*. Table 1 also summarizes the currently known variation in these characters in *A. indomitus*.

We also take this opportunity to correct some errors in the diagnosis of *A. indomitus* by Smith and Ferrari-Castro (2008). Those authors gave the subcaudal range as 37–41 (on p. 59) and 37–40 (on p. 60) and they gave the number of dorsal scale rows at midbody as 24–25 for the two *A. indomitus* they examined. Those numbers should have been 28–37 (subcaudals) and 23–25 (dorsal scale rows at midbody, respectively) as correctly noted by Smith and Ferrari-Castro (2008) in the remainder of the description. Also, Smith and Ferrari-Castro (2008:60) stated "*Atropoides indomitus* has fewer ventral scales than most of its congeners, 140 (vs. 138–155)." Actually, *A. indomitus* has more ventral scales than most of its congeners (as correctly stated by Smith and Ferrari-Castro in their abstract and resumen).

The new *Atropoides indomitus* locality in El Paraíso is in a low mountain range (Cerro Quiebra Cajón) northeast of Mapachín and about 15 km SE of Danlí (13.9830°N, 86.4910°W). This new locality lies about 170 km SSW of the species' type locality and about 135 km S of the paratype locality (Fig. 1). The snakes were collected between 850 and 1150 m elevation during May and September (elevation and date of collection of UNAH 4425 not known). MVZ 267165–67 and UNAH 5651 were all collected on the ground during the day in second growth grassy areas being cleared by local workers. The area originally was covered by a mixture of pine-oak forest and broadleaf rainforest (Premontane Wet Forest of Holdridge, 1967).

The new locality in El Paraíso, Cerro Quiebra Cajón, is an isolated and very small mountain range that is completely surrounded by elevations below 800 m that contain subhumid forest conditions seemingly unsuited for *Atropoides* populations. Other isolated and relatively low elevation mountain ranges occur between Cerro Quiebra Cajón and the other known localities for *A. indomitus*. However, most of those mountains contain the subhumid pine forests that cover most interior mountain ranges in central Honduras. These pine forests contain a depauperate reptile fauna consisting primarily of species that also occur at lower elevation subhumid conditions in the interior of Honduras. The low levels of mitochondrial variation between the El Paraíso population and those from the vicinity of its type locality suggests that there was probably some recent gene flow across this portion of Honduras, thus the populations are likely to have only recently separated. Several isolated mountain ranges with pockets of humid vegetation that conceivably could contain remnant populations of *A. indomitus* do occur between the El Paraíso locality and that of the paratype in northwestern Olancho. Thus, suitable localities in Montaña El Chile (El Paraíso and Francisco Morazán), Sierra de Misoco (Francisco Morazán and Olancho), Montaña El Armado (Olancho), Montañas del Flor (Francisco Morazán), and Montañas de Yoro (Francisco Morazán and Yoro) could be explored for other populations of *A. indomitus*. In addition, the proximity of the El Paraíso locality to Nicaragua suggests the possibility that *A. indomitus* might eventually be discovered in that country.

MVZ 267165 consumed a field mouse (*Peromyscus* sp.) that was placed alive in the small plastic bucket in which the snake was temporarily housed. Nothing else is known about diet or reproduction in this species.

Acknowledgments.—Collecting (Dictamen DVS 016–2009) and exportation (Constancia 011–2011–DVS-ICF) permits were issued by I. Acosta, C. Cárcamo, and S. Laínez of the Instituto Nacional de Conservación y Desarrolo Forestal, Áreas Protegidas y Vida Silvestre, Tegucigalpa (ICF). Anibal Rodriguez Casco of Mapachín, El Paraíso, was especially helpful to McCranie and Valdés Orellana in the collection of the new specimens. The molecular laboratory work was supported by a grant from Instituto Bioclon to E. N. Smith, who also everted the hemipenis of the El Paraíso specimen. We thank T. A. Castoe and E. N. Smith for their helpful comments on an earlier draft of the manuscript.

Applied Anatomy of the Eyelash Viper (*Bothriechis schlegelii*)

Eyelash Vipers (*Bothriechis schlegelii*), in the family Viperidae, subfamily Crotalinae (Leysner 2002), are found throughout southern Mexico through Ecuador and Venezuela (Boldy 1983) living at elevations from sea level to 1500 m (Kuch and Freire 1995). Their small size, distinctive facial appearance, colorful polychromatic variable patterns, less aggressive demeanor, and compared to other species of Crotalinae, less potent venom, make them popular display specimens (Blake 1990; Kuch et al. 1996; Leysner 2002). A modified supraocular scale gives the taxon the "eyelash" appearance that is the basis for the common name (Leysner 2002; Seifert 1983). Eyelash vipers typically attain lengths of 60–72 cm (Blake 1990; Leysner 2002; Seifert 1983; Werman 1984). Their relatively small size and availability contribute to their suitability as a representative model for studies of South American neotropical arboreal pit vipers.

Knowledge of species-specific major organ topology informs studies of taxonomy, phylogeny, life history, ecology, growth and development, adaptive physiology, and provide landmarks in surgical procedures (Blackburn 1998; Gentilli et al. 2009; Pizzato et al. 2007; McCracken 1999; Travaglia-Cardoso et al. 2010; Vincent et al. 2004). General organ topology has been described in various taxa of snakes, including *Heterodon platyrhinus*, *Boa constrictor*, *Pantherophis guttatus*, and *Morelia spilota spilota*, demonstrating taxonomic variations in organs (Funk 2005; Kellicott 1898; McCracken 1999). This study describes the topology and dimensions of the major organs of *B. schlegelii*.

Methods and Materials.—Twenty-seven frozen specimens of *B. schlegelii* (15 females, 12 males) used in this study were animals that died over several years in a private breeding colony and were donated to North Carolina State University's College of Veterinary Medicine. Background source data and medical histories on individual snakes were unavailable. The total length of the vipers examined ranged from 49 to 81.4 cm. Prior to study, each frozen carcass was individually defrosted in a cool room (7.7°C) for 24 h. An external examination recorded color phase (red, yellow, or green), and any signs of trauma or external abnormalities were noted. The cloaca was probed using a 20-gauge 6.3 cm blunted needle (Covidien, 15 Hampshire Street Mansfield, Massachusetts 02048, USA) inserted caudally to establish the full depth of the posterior cloacal pocket. Results were recorded as the number of ventral scales the probe extended past, starting from the insertion point at the vent opening and tallying to the nearest ventral scale the probe could be advanced as detected by palpation. Probing was performed as a secondary assessment technique in evaluating whether or not differences in tail length could be used for determining the sex of animals in a field setting. Each snake was then placed in ventral recumbency on a flat level dissection table and straightened to minimize positional deviations, but without applying tension. The head was secured to the dissection table with surgical tape (Covidien) to prevent any minor movement. A plastic flexible measuring tape was anchored in a straight line on the dissection table, adjacent and parallel to the snake, with the 0-cm mark positioned at the most rostral point of the head. All measurements were taken to the closest millimeter. External measurements recorded for each snake included the total body length, ([TBL] measured from the tip of the rostrum to the distal tip of the tail), the body length, ([BL] measured from the tip of the rostrum to the anterior margin of the cloaca), and the greatest width of the dorsal skull ([SW] measured across the quadrate bones). Based on an obvious break in the data distribution, the snakes were arbitrarily categorized as large (over 50 cm BL [N = 17]) or small (snakes under 50 cm BL [N = 10]).

Measured specimens were repositioned into dorsal recumbency and an incision made along the entire length of the animal's ventral midline. Internal measurements were taken using the anchored measuring tape adjacent to the specimen. The distance between the tip of the rostrum and the anterior and posterior poles of the heart, lung, liver, stomach, right and left kidney, and gonads were recorded to the nearest millimeter. Ovary and oviduct were considered as a single organ cluster for the purposes of this study, and measured from the anterior pole of the ovary to the posterior pole of the oviduct or last follicle, if follicles were present**.** The number of follicles in right and left oviducts were counted for each female and compared between sides. There was difficulty discerning the junction of lung tissue and the air sac. The posterior pole of the lung was defined by and

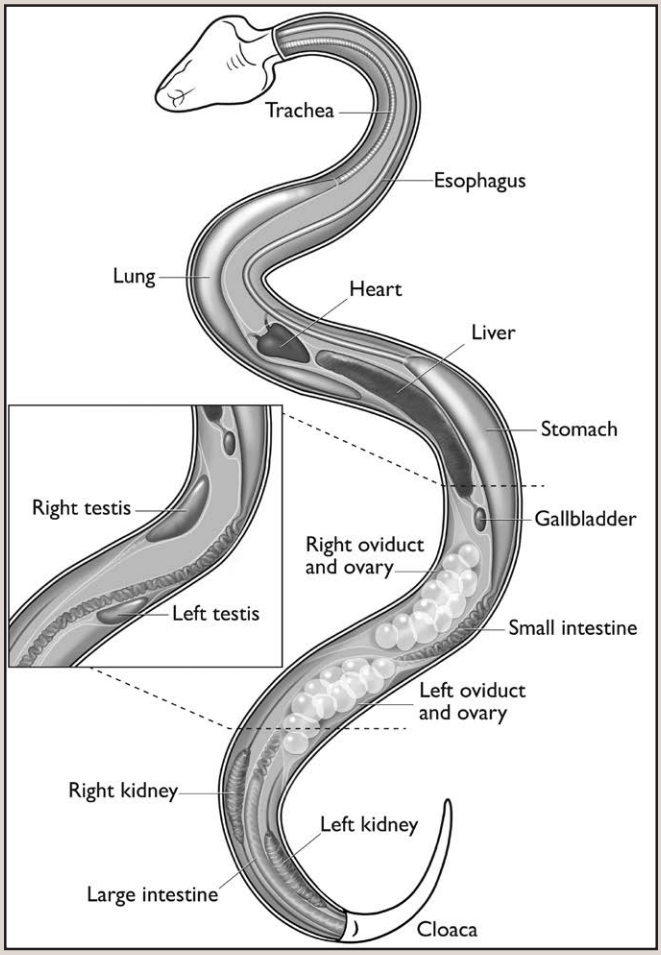

FIG. 1. Illustration of internal anatomy of *Bothriechis schlegelii.*

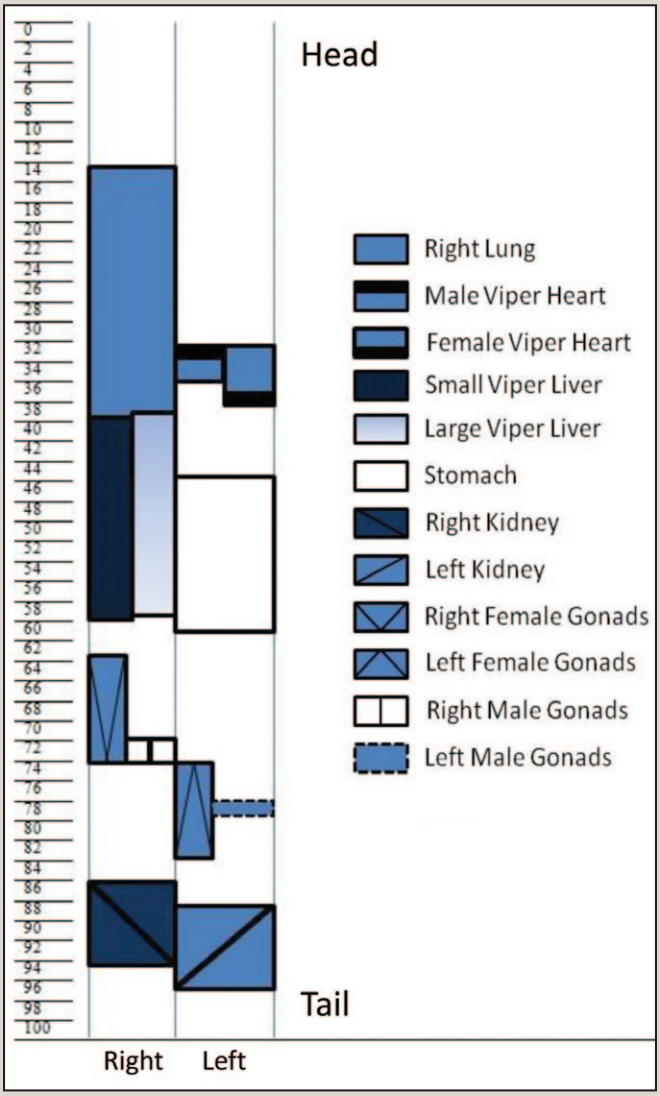

FIG. 2. Organ topography of *Bothriechis schlegelii* expressed as a percentage of Body Length (BL) (Y axis).

measured to the loss of gross vascularization in the pulmonary tissue.

The internal organ measurements were converted to a percentage of the body length (BL) for each individual snake (X = measurement / BL) × 100), and rounded to the nearest tenth of a percentage point (McCracken 1999). The lengths of individual organs were calculated by subtracting the measured position of the anterior pole of each organ from the measurement of the location of the posterior limit of that organ. The tail length [TL] was also a calculated rather than measured value, achieved by subtracting the BL from the TBL for each snake.

The measured and calculated data medians and ranges of all organ positions as a percentage of body length were plotted on an axis to better appreciate their distributions. The nonparametric Wilcoxon rank sums test using JMP software (SAS Institute Inc. 100 SAS Campus Drive Cary, North Carolina, 27513-2414, USA) considering a $P < 0.05$ as statistically significant was used to evaluate the measured and derived relative position data for all snakes analyzing for differences by sex, color phase, and size group.

Results.—The arbitrary size groups were comprised of essentially equal numbers of snakes of each sex, with the sex ratio in the small snake group being 5.5 and in the large snake group 7.10. Statistically significant differences were observed between sexes for gonad size and location, posterior cloacal sac depth, heart length, and skull width. The only statistically significant differences in calculated organ positions identified between size groups was liver length and no differences were noted between color morphs. The depth of the cloacal pocket measured as the number of subcaudal scales was consistently deeper (7 subcaudal scales with a range of 3–14) for males than for females (2 subcaudal scales with a range of 1–5 [$P < 0.0001$]). This was expected as males commonly probe to a deeper depth than females (Cover 1984; Denardo 2006; Laszlo 1975).

Fig. 1 illustrates the internal organ anatomy of a prototypical Eyelash Viper. Fig. 2 presents the organ positions expressed as a percentage of BL. The anterior extent of the single right lung is consistently near the base of the skull with a median (range) percentage of BL of 14.5 (9.8–19.1) %. The lung extends posteriorly to a median of 39.5 (33.9–44.0) % of the BL. The trachea extends and is incorporated into nearly the entire length of the lung. The heart is situated near the caudal aspect of the lungs with the anterior aspect of the heart at a 32.6 (29.6–35.9) % of the BL and extends caudally to 36.1 (33.0–8.5) % of the BL. There was a statistically significant difference in heart lengths between sexes, with female vipers having longer hearts 1.9 (1.1–3.1) cm versus males 1.4 (1.1–2.6 [Wilcoxon Ranked Sum $P = 0.0328$]) cm. The anterior aspect of liver is located at 39.7 (35.0–42.1) % of the

BL just caudal to the posterior aspect of right lung and ends at 59.8 (55.6–64.2) % of the BL. There was a statistically significant difference in liver lengths between small and large vipers, with small vipers having shorter livers 9.9 (7.6–17.1) cm compared to large vipers 11.8 (9.5–14.6 [Wilcoxon Ranked Sum $P = 0.0096$]) cm. The anterior extreme and most of the stomach overlaps the liver at 46.0 (39.2–53.6) % of the BL, with only the posterior aspect of the empty stomach extending beyond the liver. The anterior aspect of the right kidney is positioned at 86.8 (83.5–89.6) % of the BL and ends at 95 (92.9–97.3) %. The left kidney is positioned just caudal to the posterior aspect of the right kidney at 88.2 (85.4–90.4) % and ending caudal to the right kidney at 96 (93.7–98.7) % of the BL. There was a statistically significant difference in skull widths between sexes, with female vipers having wider skulls (mean 2.9 cm; range 2.0–4.1) than males (mean 2.0 cm; range 1.5–4.5 [Wilcoxon Ranked Sum $P = 0.0059$]) cm.

The right ovary and oviduct are located at the posterior aspect of the liver at 64.2 (56.3–71.9) % and end at 75.5 (69.6–79.5) % of the BL. The left ovary and oviduct overlap the right ovary and oviduct, starting at 74.5 % of BL (68.5–95.5) and ending at 84.3 (80.3–98.7) % of the BL. These data did not have a normal distribution (Wilkes Shapiro, $P = 0.005$ for starting point and $P = 0.0038$ for end). There was no statistically significant difference between the lengths of the left and right ovary and oviduct (Wilcoxon Ranked Sums, $P = 0.4552$). The mean number of follicles was the same for both the left and right ovaries and oviducts, 3–4 on each side.

The right testes also overlapped the liver, starting at 72% BL (66–75.5 %) and ending at 74.5 (67.8–76.9) % of the BL. The left testes are located caudal to the right testes, starting at 78.3 (67.9–80.7) % of the BL and ending at 80.4 (69.6–83.6) % of the BL. These data did not have a normal distribution curve (Wilkes Shapiro, $P = 0.004$ for starting point and $P = 0.02$ for end). There was a statistically significant difference in length between the right and left testis (Wilcoxon Signed Ranked test $P = 0.0204$) with the right being larger than the left.

Discussion.—The organ topology in *B. schlegelii* is similar to the anatomical descriptions of other snakes (Ackerman 1997; Chiodini et al. 1982; Evans 1986; Funk 2005; Girling and Raiti, 2004; Kellicott 1898; McCracken 1999; Rhan 1942). The absence of the left lung in *B. schlegelii* is typical of Viperidae and other families having vestigial or no left lung (Colubridae, Xenopeltidae, Loxocemidae, Pythonidae, and Boidae) (Gans and Gaunt 1998; Kellicott 1898; Wallach 1998). No differences were observed in length or position of the right lung, stomach, and kidneys with respect to sex, color scheme, or size of the viper. Species belonging to the genera *Thamnophis* and *Diadophis* have been described as possessing a longer right kidney than the left (Bishop 1959; Gans and Parsons 1977; Myers 1965), however. right and left kidney lengths did not differ in *B. schlegelii*. We did not observe nor expect any differences in anatomic locations of organs among different color morphs of *B. schlegelii*. Offspring are generally polychromatic throughout the litter.

Determining certain organ borders might be a source of variability in some measurements collected for our study. The right lung of the snake has been described as having no distinct end point, only being divided into the vascular portion and avascular portion (Gans and Gaunt 1998). The stomach presents similar challenges because there is no distinct grossly appreciable anatomical separation between stomach and esophagus (Gans and Gans 1978). In our study organ limits were determined by a single observer (EOC) for all specimens, thus avoiding inter-observer error. Variations in observer assessment of organ borders might result in minor differences in absolute organ locations in relation to body length.

The livers of vipers categorized as large in our study had longer livers relative to body length compared to vipers we categorized as small. Though it is tempting to assign this difference to age differences, the two size categories we used for our study were determined by a natural break in the data set and do not necessarily reflect differences among adult, juvenile, or neonatal animals. Based on published literature, establishing the average adult size of wild *B. schlegelii* as 50 cm TBL (Seifert 1983) and considering the smallest viper in our study was 49 cm TBL, it is likely that all of the vipers we studied were adult animals. Similarly, the sex ratios in the two arbitrary size groups were similar suggesting the difference in liver size is unlikely to be a gender characteristic. If not age or gender, the seasonality at time of death might have influenced the size of the liver in our dataset. Seasonal changes in liver size with specimens examined in periods of increased feeding (summer) having larger livers are described for *Thamnophis sirtalis parietalis* (Aleksiuk and Stewart 1971; Gans and Gaunt 1998). Consumption of food can affect internal viscera size (Andersen et al. 2005; Grossmann and Starck 2006; Starck and Beese 2001; Starck and Beese 2002). Imaging studies have documented rapid postprandial enlargement of the liver, up to 1.5 times baseline with return to fasting size 7–10 days after feeding in *Python molurus bivittatus, Thamnophis sirtalis parietalis*, and *Dasypeltis scabra* (Grossmann and Starck 2006; Starck and Beese 2001; Starck and Beese 2002). If similar changes occur in *B. schlegelii*, which has a similar "sit and wait" foraging strategy to the species studied, this could explain the variation in liver size seen in our study (Starck and Beese 2002). Feeding records were not available for the specimens we studied.

Female viper hearts were statistically longer than those of males in our study. We did not examine the size of individual atria, the ventricle or the weight of the hearts in our specimens. There is at least one report of increased food consumption being related to increased heart mass in *Python molurus bivittatus* (Andersen et al. 2005). We have no data to suggest that females in our study were fed more frequently or greater amounts than males.

Asymmetry of snake gonads has been well documented in the literature, establishing the right testis, ovary and oviduct positioned anterior to the left testis, ovary and oviduct in many species (Blackburn 1998; Funk 2005; Kellicott 1898; Girling and Raiti 2004; McCracken 1999; Pizzato et al. 2007; Rhan 1942; Werner and Drook 1967) This asymmetry is thought to be further exaggerated in arboreal species compared to terrestrial species based on studies of Indo-Australian pythons and boids (Lillywhite and Henderson 1993; Pizzato et al. 2007). Linear displacement of the gonads in arboreal snakes has been postulated to support larger embryos with minimal distension of the coelomic cavity, thereby reducing impacts of gravidity on locomotion (Blackburn 1998; Nunes et al. 2010; Pizzatto et al. 2007; Travaglia-Cardoso et al. 2010), and improving support of the body on thin tree branches (Blackburn 1998; Lillywhite and Henderson 1993; Pizzatto et al. 2007). Our data would be consistent with an arboreal survival strategy for female *B. schlegelii*. Though follicle number and size are reported to be greater for the right ovary and oviduct in several snakes, including *Thamnophis radix, Xenochrophis vittata, Natrix sipedon, Natrix rhombifera*, and *Ptyas mucosus* (Bergman 1950; Betz 1963; Bragdon 1953; Cieslak 1945; Das 1960), this was not the case for *B. schlegelii*. We observed no statistically

significant difference in the length or the number of follicles of the left and right ovaries in the females we dissected. We did, however, observe a statistically significant longer length of the right testis compared to the left in male *B. schlegelii*. This has been previously reported in *Leptotyphlops phillipsi* and *Vipera berus* (Gans and Parsons 1977; Werner and Drook 1967).

Sexually dimorphic characteristics observed in *B. schlegelii* included expected differences in cloacal pocket depth between males and females, with the probe inserting further into the distal tail of males than females. This is commonly observed in most snake species (Cover 1984; Denardo 2006; Laszlo 1975).

Another sexually dimorphic characteristic observed in *B. schlegelii* in our study was skull width. The skulls were found to be wider in females than in males. This trait has been documented in other species including, *Thamnophis* spp. *Acrochordus arafurae*, and *Laticauda colubrina* (Houston and Shine 1993; Shine and Crews 1988; Shetty and Shine 2002). Though our data showed a statistically significant difference between male and female snakes for this trait, there was a great deal of overlap of the male and female measurements, suggesting that it will not be practical to use this measurement for differentiating sex in *B. schlegelii*.

Tail length has also been reported to be a secondary sex characteristic in some species of snakes, with male *Bothrops insularis*, *Vipera aspis*, and *Elaphe longissima* reported to have longer, thicker tails than females (Bonnet et al. 1998; Cardoso et al. 2010; Denardo 2006; Laszlo 1975; Travaglia-Cardoso et al. 2010). Our study found no statistically significant difference in tail length between sexes in *B. schlegelii* and tail length would not be a reliable method for determining sex in this species.

Hoop Net Escapes and Influence of Traps Containing Turtles on Texas Spiny Softshell (*Apalone spinifera emoryi*) Captures

Hoop nets are probably the most commonly used device for sampling aquatic turtles because they 1) are lightweight, easily portable in large numbers, and comparatively easy to hide; 2) provide easily quantifiable results; and 3) do not require intensive labor to operate (Conant and Collins 1998; Lagler 1943; Thomas et al. 2008). Several authors have reported escapes from hoop nets (Brown et al. 2011a; Frazer et al. 1990; Gamble 2006; Koper and Brooks 1997). Escape rates may be species-specific (Frazer et al. 1990) and turtles may not only be attracted by bait placed in the trap, but also influenced, either positively or negatively, by other turtles present in the trap (Cagle and Chaney 1950; Frazer et al. 1990; Ream and Ream 1966). Of particular interest is the suggestion that hoop nets are a male-biased sampling method because males are attracted to females caught in traps (Cagle and Chaney 1950; Vogt 1979). Frazer et al. (1990) tested this hypothesis and caught more Painted Turtles (*Chrysemys picta*) in traps containing females than in traps without turtles. However, Vogt (1979) found no differences in number of male Painted Turtle captures between female-baited and male-baited traps. Because few studies have been conducted on this topic and these studies have obtained conflicting results, it is currently unclear whether turtles present in traps bias future captures.

Differential escapes from and attraction to hoop nets could also be an influential source of bias when estimating population size and structure of freshwater turtles. We are aware of only one study that directly assessed differential escapes from hoop nets. Brown et al. (2011a) found that significantly more female than male Red-eared Sliders (*Trachemys scripta elegans*) escaped hoop nets in lentic water bodies. Thus, differential escapes rather than differential attraction could explain why hoop nets are perceived to be male-biased. However, the applicability of these results to other taxa and aquatic environments is currently unknown. The purposes of our experiment were to determine if sex or body size influenced Texas Spiny Softshell (*Apalone spinifera emoryi*) escapes and to determine if "seeded" traps (i.e., traps with turtles placed in them) attracted more turtles than unseeded traps.

Materials and methods.—In the summer months of 2010 through 2012 we trapped and seeded turtles at three sites along the Rio Grande in Texas. In 2010, the study site was Big Bend National Park (29.18304°N, 102.9907°W), Brewster Co. In 2011, the study site was Black Gap Wildlife Management Area (BGWMA; 29.56139°N, 102.77798°W), Brewster Co. In 2012, the study sites were BGWMA and Southmost Preserve (25.84070°N, 97.38863°W), Cameron Co. The stretch of Rio Grande in Brewster Co. contains abundant Texas Spiny Softshells and Big Bend Sliders (*Trachemys gaigeae*), with a potentially growing population of non-native Red-eared Sliders (Jackson 2010), while the stretch of Rio Grande in Cameron Co. contains abundant Texas Spiny Softshells and Red-eared Sliders (Brown et al. 2011b). In addition to trapping the Rio Grande to obtain individuals for this experiment, we also trapped adjacent lentic water bodies to increase the sample size.

We used the same 76.2-cm diameter single-throated, single-opening, widemouth hoop nets with 2.54-cm mesh used by Brown et al. (2011a). Distance between the traps ranged from 5–100 m depending on availability of vegetation to secure the traps. All traps were set with entrances facing downstream (Lagler 1943) and baited with canned sardines placed in non-consumable containers containing holes for scent dispersal (Brown et al 2011a; Gamble 2006). We replaced bait every two days. In 2010, we completed 160 trap-days from 4-8 June. In 2011, we

completed 449 trap-days from 14–19 June. In 2012, we completed 132 trap-days at BGWMA, from 8–10 May and 65 trap-days at Southmost Preserve from 27 May–8 June. We excluded all trap-days prior to seeding turtles (Table 1).

For all captured turtles we recorded carapace length and width, plastron length and width, and body depth to the nearest 1.0 mm using tree calipers (Haglof, Madison, Mississippi) and determined mass to the nearest 10 g using spring scales (Pesola, Baar, Switzerland). Sex was determined using secondary characteristics; for Texas Spiny Softshells, the pre-cloacal portion of the tail lies beyond the edge of the carapace in males and before or at the edge of the carapace in females (Berry and Shine 1980). We marked softshells by engraving individual numbers on the posterior end of the carapace and marked sliders by notching marginal scutes on the carapace using a rotary tool (Dremel, Racine, Wisconsin). After softshells were processed, we placed them in the hoop nets at random, with one turtle used per trap and each turtle used only one time for the experiment. We seeded between one and 26 traps per day. Therefore, not all traps were seeded at all times, which gave us the opportunity to test if seeded traps attracted more turtles than unseeded traps. Every 24 h we recorded escapes from seeded traps as well as new captures in both seeded and unseeded traps and we released the original turtles used to seed the traps. We conducted this experiment using a total of 107 seeded trap-days and 481 unseeded trap-days. Of the 107 turtles, 88 were originally captured in the river, while the remaining turtles were originally captured in adjacent lentic water bodies.

We used logistic regression to determine whether escapes were sex- or size-biased (Lindsay 1995). We combined the data from all years and tested two models. The first model included body depth as the predictor and hoop net escape as the binary response variable and the second model included both body depth and sex as predictors (i.e., juveniles were removed from this analysis). Likelihood-ratio tests were used to determine if the predictors significantly increased the fit of the data relative to the intercept-only model (i.e., deviance greater than chance alone). We used a randomization test to determine if seeded traps attracted more turtles than unseeded traps (Sokal and Rohlf 1995). All statistical analyses were performed in R 2.8.1 (The R Foundation for Statistical Computing, Vienna, Austria).

Results.—Eight of the 107 softshell turtles escaped (7%), including 6 males (8% of males), one female (3% of females), and one juvenile. Body depth was a significant predictor in the model that included only body depth as a predictor, with smaller turtles being more likely to escape (Deviance $\chi^2_{1,105} = 52.35$, $P = 0.03$; AIC = 56.35; Fig. 1). However, body depth was not a significant predictor when sex ratio was added to the model (Deviance $\chi^2_{1,103} = 48.81$, $P = 0.10$; AIC = 58.14). Sex was not a significant predictor (Deviance $\chi^2_{1,102} = 48.59$, $P = 0.64$). In addition to the 107 softshells, we captured 39 sliders during this study. Seeding traps did not affect Texas spiny softshell captures ($P = 0.52$) or overall turtle captures ($P = 0.87$).

Discussion.—We found a much lower escape percentage for Texas Spiny Softshells in a river system (7%) than Frazer et al. (1990) reported for Painted Turtles and Snapping Turtles in a lentic system (80% and 25%, respectively) and a higher percentage than Brown et al. (2011a) found for Red-eared Sliders in a lentic system (3.6%). In addition, Brown et al. (2011a) reported escapes were sex-biased, with females escaping more than males, but not size-biased, whereas we obtained the opposite results. The conflicting results among studies indicate there are interspecific differences in escape probability and potentially habitat-influenced differences. Different types of water bodies could potentially change the behavior of turtles within traps and, as a consequence, escape probabilities.

Our study does not support the hypothesis that turtle captures in hoop nets are influenced by the presence or absence of other turtles in the trap. This is contrary to Frazer et al. (1990), who found more *C. picta* in traps that already contained turtles. Thus, interspecific differences may exist for turtle attraction as well as escapes. Unfortunately, due to a low sample size for females, we were unable to determine whether or not sex of the captured turtle matters in terms of potential to attract other turtles. Based on results from the small number of studies that have investigated the efficacy of sampling freshwater turtles using hoop nets, it is clear that there is still much knowledge to be gained.

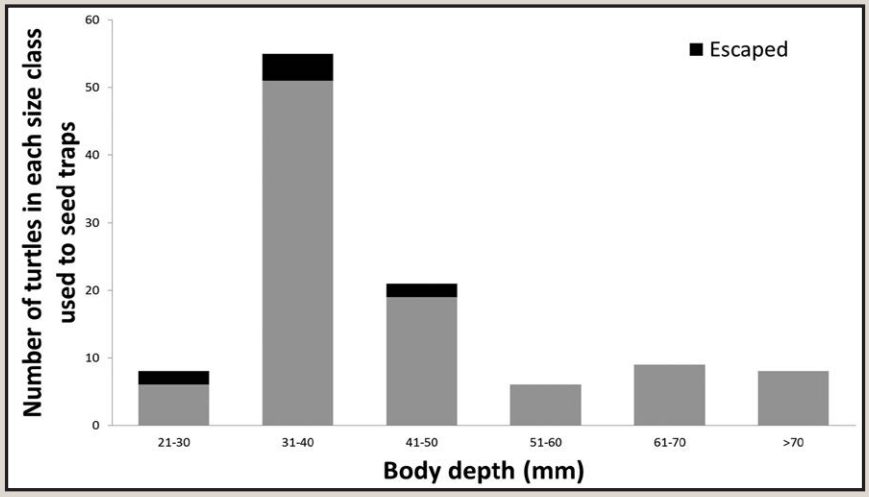

FIG. 1. Total number of Texas Spiny Softshells (*Apalone spinifera emoryi*) used to seed hoop nets along the Rio Grande with numbers that escaped by body depth. Body depth was a significant predictor in the model that included only body depth as a predictor, with smaller turtles being more likely to escape (Deviance $\chi^2_{1,105} = 52.35$, $P = 0.03$).

TABLE 1. Study locations, number of trap days (excluding initial trap days prior to seeding traps), and number of turtles used to seed traps each year at sites used to investigate hoop net escapes and attraction for Texas Spiny Softshells (*Apalone spinifera emoryi*) in the Rio Grande river in Texas.

Year	Study site	Number of trap days	Number of seeded turtles
2010	Big Bend National Park	120	41
2011	Black Gap Wildlife Management Area	369	29
2012	Black Gap Wildlife Management Area	72	26
2012	Southmost Preserve	36	11
Total		597	107

Acknowledgments.—We thank J. R. Dixon, J. Dixon, A. Villamizar, B. DeVolld, J. Tokarz, and J. Duvall for assistance with checking and seeding traps. We thank M. Pittman and the Texas Parks and Wildlife Department for allowing us to reside at Black Gap Wildlife Management Area and use the property as a study site. We thank M. Pons, Jr. and the Nature Conservancy of Texas for allowing us to reside at Southmost Preserve and use the property as a study site. We thank the National Park Service for allowing us to use Big Bend National Park as a study site. This study was conducted under Texas Parks and Wildlife Department Permit SPR-0102-191. This research was approved by the Texas State University-San Marcos Institutional Animal Care and Use Committee (protocol 1010_0501_09).

Relationships of Body Size and Male Melanism to Biting Propensity in Red-eared Sliders (*Trachemys scripta*)

Biting is a primitive and versatile behavior of turtles that likely evolved for feeding but is also used for defense and during social interactions (Davis and Jackson 1973). Biting during social interactions has been documented in numerous turtle species (Bury and Wolfheim 1973; Bury et al. 1979; Carpenter 1966; Ernst and Barbour 1992; Lardie 1983; Mafli et al. 2011; Schofield et al. 2007). The standard English names of snapping turtles, *Chelydra serpentina* and *Macrochelys temminckii,* reflect their tendency for defensive biting directed at human handlers. Bite force is generally correlated with body size (Herrel et al. 2002). Therefore, it is not surprising that adults sometimes use defensive biting in situations where juveniles do not (Pritchard 1989) or that larger turtles often prevail in social interactions that involve biting (Carpenter 1966; Lindeman 1999).

The Red-eared Slider (*Trachemys scripta*) is a widely distributed freshwater turtle that occurs in many aquatic habitats (Ernst et al. 1994). Lindeman (1999) observed that aggressive interactions among basking *T. scripta* resulted in larger turtles successfully displacing smaller turtles twice as often as smaller turtles displaced larger turtles. Turtles utilized several aggressive behaviors including biting, clawing and pushing when competing for basking sites (Lindeman 1999). These data support the hypothesis that aggression increases with increasing body size.

Another hypothesis regarding aggression that is specific to male *T. scripta* is that aggression increases as males become melanistic (Cagle 1950; Cahn 1937; Carr 1952; Lardie 1983; Parker 1990; Tucker et al. 1995). This hypothesis is attractive because in diverse taxa, including other turtles (Mafli et al. 2001), there is a correlation between aggressiveness and degree of melanism (Ducrest et al. 2008). Male *T. scripta* exhibit ontogenetic melanism (Lovich et al. 1990). As males approach the body size of sexually mature females in the local population, the green and yellow pigmentation on the integument and shell is replaced with melanin (Cagle 1950; Lovich et al. 1990; McCoy 1966). Although the function of melanism in *T. scripta* is not understood, several hypotheses have been presented including thermoregulation (but see Boyer 1965; Gronke et al. 2006), sexual selection, intra- or interspecific communication, and non-adaptive by-product of hormonal changes (Lovich et al. 1990). Of these, the hypothesis with the most support is the sexual selection hypothesis. In laboratory experiments examining courtship behavior, alternative mating tactics were observed. Nonmelanistic males initiated titillation, a precopulatory behavior consisting of rapid

vibration of the foreclaws against the head of a female turtle (Cagle 1950; Jackson and Davis 1972) while melanistic males used chasing and biting as courtship behaviors (Thomas 2002). Anecdotally, melanistic male *T. scripta* have been described as aggressive and socially dominant (Cagle 1950; Cahn 1937; Carr 1952; Lardie 1983; Parker 1990; Tucker et al. 1995).

In the course of our research we handled hundreds of *T. scripta* across the complete range of body size for this species. This provided an opportunity to test two hypotheses: 1) the propensity to bite increases with body size, and 2) the propensity to bite increases with melanin deposition. During 2007–2008 we recorded biting attempts by *T. scripta* during handling. With these data we report the frequency of biting attempts, explore ontogenetic, intersexual and intrasexual differences in biting attempts, and test whether biting attempts during handling can be predicted from body size or melanism.

Materials and Methods

Study Area.—Our study area consisted of three ponds in Canadian County, Oklahoma, USA. The largest pond (35.6643°N, 97.6896°W; WSG84) was 2.1 ha. Two smaller ponds of 0.9 ha each were located adjacent to one another and within 1.07 km of the larger pond (see Stone et al. 2005 and Beshara 2009 for a detailed description of the study area).

Field Methods.—We trapped turtles during March–July 2007 and April–October 2008. We used double-throated hoop nets of varying sizes, with mesh sizes of 2.5 or 3.8 cm, baited with sardines. Traps were set overnight around the perimeter of ponds an average of four days per month, for a total of 377 trap days. Turtles were processed and released the following day.

Captured turtles were held in buckets and processed individually. The number of turtles captured in a net ranged from 0–25. All turtles in a given net were held in the same bucket until processing. Depending on the number of turtles captured, holding time varied from 10–90 min. We did not test the effect of length of holding time on biting propensity. Individuals were released immediately after processing.

Each turtle was removed from the bucket, dried with a towel, and tapped on the nose to provoke a response. If the turtle opened its mouth or attempted to bite, we recorded the response as a biting attempt. After testing for biting, we measured a series of traits for each turtle. Midline plastron length (MPL) was measured with dial calipers to the nearest 0.1 mm and used as an estimate of body size. We used body size and the presence or absence of secondary sexual characteristics (Cagle 1950) to determine the sex of each turtle. We classified turtles having elongated foreclaws and an enlarged postanal tail as males. Turtles that did not have male secondary sexual characteristics were classified as juvenile if MPL was <100 mm, juvenile female if MPL was 101–165 mm, and adult female if MPL was ≥166 mm. Size thresholds for these categories were obtained from our unpublished data but are consistent with values published elsewhere (Cagle 1950; Dunham and Gibbons 1990).

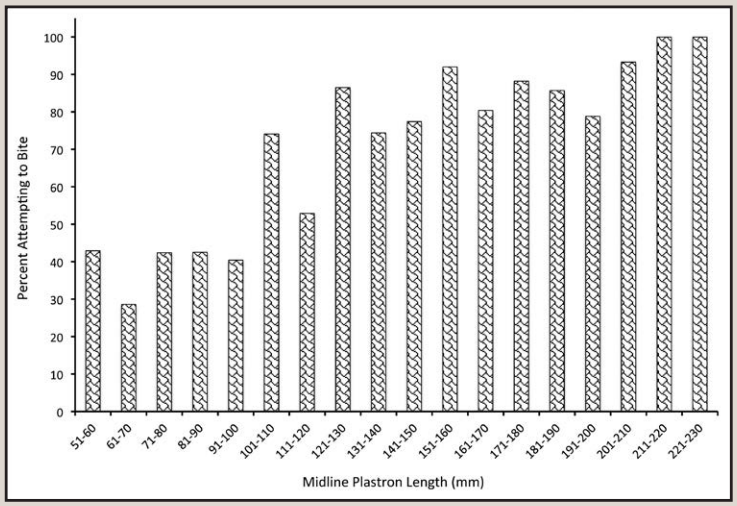

Fig. 1. Biting frequency as a function of midline plastron length in *Trachemys scripta*.

Table 1. Biting attempts by *Trachemys scripta* of different age and sex classes.

Class	N	Number attempting to bite	Percent attempting to bite	Mean ± SE MPL (mm)
Melanistic males	69	62	89.9	172.2 ± 1.52
Partially melanistic males	66	59	89.4	155.3 ± 1.27
Non-melanistic males	158	118	74.7	126.9 ± 1.35
Females	119	100	84.0	192.0 ± 1.36
Juvenile females	49	30	61.2	136.6 ± 2.70
Unsexed juveniles	132	54	40.9	82.4 ± 1.00

Table 2. Logistic regression analysis of the effect of plastron length on biting propensity in *Trachemys scripta*.

Group	P	Odds ratio	95% Wald C.L.	% Concordance	C (area under ROC curve)
All Turtles	<0.0001	1.023	1.018–1.029	73.8	0.740
Adult males	<0.001	1.028	1.015–1.042	67.5	0.678
Melanistic males	0.5089	1.021	0.960–1.087	59.0	0.600
Partially melanistic males	0.3927	1.035	0.956–1.112	60.5	0.615
Non-melanistic males	0.0086	1.032	1.008–1.057	63.0	0.633
All females	<0.0001	1.026	1.013–1.039	70.3	0.705
Adult females	0.0614	1.037	0.998–1.078	62.1	0.624
All juveniles	0.0026	1.017	1.006–1.029	60.4	0.608
Juvenile females	0.0231	1.040	1.005–1.077	70.2	0.706
Unsexed juveniles	0.6249	1.008	0.977–1.039	51.0	0.525

Male melanism was determined by the degree of melanin deposited on the shell and the degree that the line pattern on the skin was obscured. Adult males were scored as nonmelanistic (NM), partially melanistic (PM), or fully melanistic (MM). Nonmelanistic turtles had bright, defined line patterns on the integument with no melanin deposited on the plastron. Partially melanistic turtles had line patterns that were still visible, but noticeable melanin deposited on both the integument and the plastron. In fully melanistic turtles, the line patterns were completely obscured by melanin, and the plastron was completely melanized. These three stages are similar to the categories of progressive melanism described by Tucker et al. (1995).

Statistical Analyses.—We used logistic regression to determine whether biting attempts were predictable from plastron length or degree of melanism in adult males. Logistic regression was used to model the relationship between plastron length and biting attempts for all turtles, all adult males, nonmelanistic males, partially melanistic males, fully melanistic males, all females, adult females, juvenile females, and unsexed juveniles. We also conducted a Chi-square contingency analysis to determine whether frequencies of biting attempts were the same for nonmelanistic, partially melanistic, and fully melanistic males. We used an ANOVA to determine whether plastron length differed among the three groups of adult males. All data analyses were generated using SAS software (Version 9.1). For all statistical tests we used an alpha level of 0.05.
